Abstract

Background: Malaria is a major health problem, with over one third of worldwide populations currently at risk. Determining the genetic diversity of plasmodium parasites is essential for assessing the efficacy of antimalarial drugs and for future vaccine development. This study investigated the genetic diversity of P. falciparum merozoite surface protein 2 (MSP2), and multiplicity of infection (MOI) in different geographic regions in Sudan.

Methods: A total of 271 patients with uncomplicated malaria were recruited from four ecological sites during malaria transmission season, 2011-2013. P. falciparum was confirmed using species specific primers targeting the rDNA gene. All P. falciparum positive samples were genotyped for the major MSP2 allelic families (IC1/3D7 and FC27 MSP2 allele) using nested PCR. Multiplicity of infection and allele frequencies were determined.

Results: A total of 241 samples (88.9%) were confirmed positive for P. falciparum. The number of different MSP2 alleles were 14, 15, 13 and 12 in Khartoum, Gezira, River Nile and Red Sea states, respectively. The 3D7 allelic family was more prevalent in the states of Khartoum, Gezira, River Nile and Red Sea compared to the FC27 allelic family. Multiclonal infections were observed in 25.8% of patients, with a mean multiplicity of infection (MOI) of 1.45. MOIs were highest in the age group over 40, with an average of 2 and 1.68 in Khartoum and Gezira states, respectively, however MOIs in River Nile and Red Sea states were higher in age groups below 18, with an average of 1.37 and 1.33, respectively.

Conclusions: MSP2 allelic genotyping revealed MOI and diversity of the Sudanese P. falciparum isolates. The results of our study are expected to influence current and future malaria control strategies, since the MOI
predicts development of clinical malaria and subsequent efficacy of antimalarial treatment.

Introduction
Malaria was and still is a major health problem, with over one third of worldwide populations being at risk (World Health Organization, 2015). The burden of this disease falls the heaviest on Sub-Saharan African countries (World Health Organization, 2015). In Sudan, almost 90% of the population live under high malaria transmission levels, as recently reported by the WHO (“WHO | Sudan,” 2016; World Health Organization, 2015). Malaria in Sudan is transmitted mainly by Anopheles arabiensis and the majority of cases are due to P. falciparum (Ageep et al., 2009). The merozoite surface protein-2 (MSP2) is a highly polymorphic plasmodium membrane protein and the most expressed in the surface of the merozoite (Gerold et al., 1996). It has been long studied in vaccine trials for being accessible by the immune system (McCarthy et al., 2011). MSP2 protein is highly polymorphic, which gives an opportunity for molecular epidemiologists to differentiate between recurrent and new infections (Mwingira et al., 2011). Genetic diversity of MSP2 alleles is due to mutations and proliferation of highly polymorphic central repeats (Ferreira & Hartl, 2007). The allelic diversity of MSP2 proteins can be used to calculate multiplicity of infection (MOI), which is the number of different strains of P. falciparum co-infecting the same host and is a valuable for estimating malaria transmission level (Vafa et al., 2008). Sudan experiences a range of climate variations, from arid desert in the north, to tropical areas in the south and a short rainy season (Noor et al., 2012). The current study aimed to determine the level of genetic diversity of the P. falciparum MSP2 gene, using field isolates across different geo-ecological regions in Sudan. The study also aimed to determine the relationship between genetic diversity and the characteristics between different patients. Little has been documented regarding the molecular diversity of P. falciparum in hypno and meso-endemic regions of Sudan, in particular after adoption of ACT as antimalarial treatment.

Methods
Study areas
This study was conducted across the two geographical zones of Sudan: the semi-desert regions of the Red Sea (Northeast) and the savannah regions of Khartoum (Central), Gezira and River Nile states. It took place between August 2011 and December 2013 – peak malaria transmission is between July and December (rainy season) in the poor and rich savannah regions, but in the semi desert regions of the Red Sea, peak malaria transmission occurs between November and January, during the winter season.

Ethical statement
Ethical clearance was obtained from the scientific and research ethics committee, Institute of Endemic Diseases, University of Khartoum. Informed consent was obtained from patients, or guardians if the patient was a minor, for participation in this study. Anonymity and confidentiality of patient information were maintained throughout.

Sample collection and parasite identification
A total of 271 symptomatic malaria patients from all age groups regardless of gender were recruited from selected health facilities (Omdurman teaching hospital and Omdoom and Mubarak Zaroor health centers in Khartoum, Wad madani teaching hospital in Gezira, Zeedab, Kaboushia and Elbouga hospitals in River Nile and Unity hospital in Red Sea) during peak malaria transmission season. Patients were passively recruited from the outpatient clinics of these hospitals during the study period. Patients were diagnosed with malaria using blood film microscopy. Parasite density and hemoglobin level were measured on each sample upon collection. Thick and thin blood smears were stained with Giemsa stain. Parasite density was determined by counting the number of asexual parasites per 200 white blood cells using the formula described by Cook (Cook, 1990). The data was grouped based on the level of parasitemia, into low = 1–5,000 parasites/µl, intermediate = 5,001–10,000 parasites/µl and high = >10,000 parasites/µl.

DNA extraction and amplification of MSP2 genes
Parasite DNA was extracted from dried blood samples spotted on filter papers using a method described by Musapa et al. (Musapa et al., 2013). Plasmodium species were identified by 18S rDNA based nested PCR, using genus and species specific primers manufactured by Macrogen, Korea, as described by Snounou et al. [15]. MSP2 alleles were further amplified with slight modification of the standardized nested-PCR protocols described previously by Snounou et al. (Snounou et al., 1993)

Electrophoresis and visualization of PCR products
The amplified PCR products were run on 2% Agarose gel (Caisson, Utah, USA) stained with 4µl ethidium bromide at 100V and 30A for 60 minutes. DNA fragments were estimated using 100 bp DNA ladder marker (Vivantis, Selangor DarulEhsan, Malaysia) and the bands were viewed under UV light using trans-illuminator (BioDoc-It UVP, Cambridge, UK).

Calculating the multiplicity of infection
The multiplicity of infection (MOI) was calculated by dividing the total number of fragments observed in MSP2 by the number of positive samples. Isolates with a single genotype were considered monoclonal infections while isolates with more than one genotype was considered multiclonal infections.

Statistical analysis
Data was analyzed using SPSS version 20 (SPSS, Inc., Chicago, IL, USA). Proportions were compared for significance using the χ2-test. The association between MOIs, parasite densities and age groups were computed using Spearman’s rank correlation coefficient. Statistical significance among MOIs and mean hemoglobin levels for the different age groups were calculated using the Kruskal-Wallis H-test at a P-value of ≤ 0.05.

Results
P. falciparum rDNA was detected in a total of 241 (88.9%) malaria patients using nested PCR (Figure 1). 158 (65.6%) were male, while 83 (34.4%) were female. The distribution of patients across the four studied states: Khartoum, Gezira, River Nile and the Red Sea was 81 (33.6%), 58 (24.1%), 47 (19.5%) and 55

Allelic polymorphism of MSP2, multiplicity of infection, distribution of multiclonal *P. falciparum* infection, and parasite density across different age groups in Sudan

Allele genotyping revealed the highly polymorphic nature of Sudanese *P. falciparum* isolates with respect to the MSP2 gene. Both IC1/3D7 and FC27 MSP2 allele types were identified (Figure 2). The total number of different sized alleles detected in this study was 42. Among them IC1/3D7 (160–400 bp) and FC27 (140–400 bp) allele families were noted. Frequencies of different MSP2 alleles and their combinations and multiplicity of infection across the study sites are shown in Table 2. The frequency of samples with only IC1/3D7 and FC27 were 56.4% (136/241), and 17% (41/241), respectively and IC1/3D7/FC27 combinations were found in 26.6% (64/241) of samples. The prevalence of IC1/3D7 and FC27 allelic types was 82.9% (200/241) and 43.5% (105/241), respectively. Multiple clones were detected in all study sites. Multiplicity of infection (MOI) was highest in *P. falciparum* infected patients from Gezira state (1.67 genotypes per infection) and lowest in those from Red Sea state (1.20 genotypes per infection) and it was statistically significant, (p-value = 0.001) (Table 2). The difference in distribution of allelic polymorphism of MSP2 was only significant for total MSP2 and FC27 (p-value = 0.002 and p-value = 0.042, respectively). However, for IC1/3D7 the result was not statistically significant (p-value = 0.89). The estimated mean MOI of all studied areas was 1.46 genotypes per infection (Table 2). There was a negative correlation between age and parasite density (Spearman rank coefficient = 0.03; p-value = 0.65), though it was not significant. The 18–40 age group had the highest mean parasite density (16354 parasites/µl, Table 3).

Relationship between multiplicity of infection, age groups and parasite densities

The distributions of *P. falciparum* MSP2 block 3 allelic types across different age groups are shown in Table 3. The prevalence of IC1/3D7 and FC27 is shown in the same table.

![Figure 1. Detection of *P. falciparum* species. There is no significant correlation between multiplicity of infection and the age group the patient is in (Spearman rank coefficient = 0.01; *P*-value= 0.50). The distribution of IC1/3D7 and FC27 according to different levels of parasitaemia is shown in Table 4. Neither the individual distribution of IC1/3D7 and FC27 nor the multiclonal isolates were significantly different among different parasitaemic groups (p-value = 0.7 and *P*-value = 0.957, respectively).

**Discussion**

Increasing our knowledge of the genetic diversity of *P. falciparum* induced malaria will certainly help us understand its pathogenesis, acquired immunity and drug resistance. 14, 15, 13 and 12 different alleles of MSP2 were identified in Khartoum, Gezira, River Nile and Red Sea states, respectively. This data is consistent with previous studies in low and unstable malaria transmission regions in eastern Sudan (A-Elbasit *et al.*, 2007), central Sudan (Hamid *et al.*, 2013), and other areas of seasonal unstable malaria transmission (Elmahdi *et al.*, 2012). 3D7 alleles were more prevalent in the four states (Khartoum, Gezira, River Nile and Red Sea) compared to FC27 alleles. This finding differs from those of previous studies in central and eastern Sudan, where FC27 was the most predominant allelic family (A-Elbasit *et al.*, 2007; Babiker *et al.*, 1997; Hamid *et al.*, 2013). In our study, 25% of studied samples were found to have mixed infections with multiple parasite clones; a result similarly reported in eastern Sudan (Babiker, 1998).

In our study, multiplicity of infection was highest in the >40 age group (with an average MOI of 2 and 1.68 in Khartoum and Gezira states, respectively), whereas the MOI was highest in the <18 age group (with an average of 1.37 and 1.33 in River Nile and Red Sea states, respectively), although the difference was not statistically significant. Recent studies on the variation of MOI with age have suggested that the influence of age on MOI is highly affected by the endemicity of malaria (Pinkevych *et al.*, 2013). This is consistent with studies that have shown an age-dependent MOI in villages with intense perennial malaria transmission (Smith *et al.*, 1999) and some areas with hypo-meso-endemic malaria transmission like Ghana (Agyeman-Budu *et al.*, 2013).

The relatively higher number of alleles detected at high parasite densities might also mean that more diverse parasite populations are present in such infections. This suggestion is partly supported by the finding that all the different allelic types were more often concurrently detected in the high-density samples (Färnert *et al.*, 2001). The present study reported that the increasing level of multiplicity was seen with increased parasite density of the samples. These findings are compatible with a previous study that has shown a clear trend of increasing parasite density with increased multiplicity for genetic markers on both genes, MSP1 and MSP2 (Peyert-Hoffmann *et al.*, 2001). The results of our study will likely influence current and future malaria control strategies since MOI can predict antimalarial treatment response (Kyabayinze *et al.*, 2008).

**Conclusions**

Allele genotyping revealed the highly polymorphic nature of Sudanese *P. falciparum* isolates with respect to the MSP2 gene. The results of our study are expected to have an influence on the current and future malaria control strategies, since MOI predicts development of clinical malaria and subsequent efficacy of antimalarial treatment.

**Abbreviations**

**Ethical statement**

The study received approval from the scientific and research ethics committee of the Institute of Endemic Diseases; University of Khartoum, Sudan. Informed consent was obtained from all participants (or from the parents/legal guardians when the participant was a minor), prior to their enrolment. All malaria patients approached in the study were treated using the standard treatment of WHO protocol for malaria (Olumese, 2017).

**Data availability**

Dataset 1: Raw data supporting the findings presented in this study. The dataset is available both in XLSX and SPPS format. DOI, 10.5256/f1000research.12585.d179181 (Mustafa *et al.*, 2017).

**Competing interests**

All authors have declared that they have no conflict of interest.

**Grant information**

This study was partially funded by the National Malaria Program Administration, Ministry of Health, the University of River Valley, Sudan and Third World Academy of Science (TWAS), Trieste, Italy [project no. 13-145 RG/BIO/AF/AC_G].

The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

**Acknowledgements**

We thank all malaria patients who participated in the study. The authors would also like to thank Prof. Muntaser E. Ibrahim, director of the Dr. Douglas Barker Molecular Biology Lab, Institute of Endemic Diseases, University of Khartoum, for hosting the molecular work and data analysis.

The article as it stands, although on an important topic specific for malaria research, needs further improvement to achieve sufficient scientific relevance for indexing. The work describes the diversity of a very polymorphic gene, pfmsp2 in \textit{P. falciparum} in various sites around Sudan adjudicating the multiplicity of infection. They compare the genetic diversity between different regions where samples were collected as well as with patients’ characteristics.

Considering the Figure 2, that should represent the results for all the samples, the results are very difficult to extract, questioning the true genotyping and consequently the MOI of the samples. The nested PCR method used is very delicate and demands a good quality of agarose gel pictures, that is not the case of Figure 2. Unless all samples were run in the same gel (which is not the case), the bands from the molecular marker has to be evident to be able to evaluate the band sizes of the samples. The families IC1 and FC27 can differ of just 50 bp difference, making the resolution of the Figure 2 an impossible task to achieve. This technical issues have to be resolved for the accuracy of the data.

In the article should also be described the malaria epidemics in the regions where the samples were collected to understand if the number of samples herein analyzed are representative.

The method to identify plasmodium species is lacking the reference and is not really understood if other species were identified.

Some of the authors of this article have published\(^1\) before submission of this manuscript a similar study on samples collected in one of the regions herein studied in the same year and the same genotyping of the msp2. They don’t mention this publication not even in the discussion section. Are some of the samples overlapping this study?

References
Is the work clearly and accurately presented and does it cite the current literature?
No

Is the study design appropriate and is the work technically sound?
Partly

Are sufficient details of methods and analysis provided to allow replication by others?
Yes
