Abstract

Priapism is an abnormal prolonged and persistent penile erection lasting more than 4 h, unrelated to sexual desire, stimulation or activity. The three types of priapism are low-flow, high-flow and stuttering. Patients with sickle cell disease (SCD) have increased risk of low-flow and stuttering priapism, but high-flow priapism is relatively uncommon in SCD. We report a case of non-traumatic refractory high-flow priapism evolving from a stuttering low-flow priapism in a patient with SCD. The patient was successfully treated by super-selective transcatheter embolization of the penile arteries with an autologous blood clot. It is proposed that the super-selective transcatheter embolization of unilateral or bilateral penile arteries with autologous blood clot is a relatively safe and effective non-surgical treatment option for high-flow priapism, even in patients with SCD, and has a low probability of developing erectile dysfunction.

Introduction
Priapism is an abnormal prolonged and persistent penile erection lasting for more than 4 h that is unrelated to sexual desire, stimulation or activity\(^{1-5}\). Priapism is categorized into three types: low-flow (ischemic, veno-occlusive), high-flow (non-ischemic, arterial), and stuttering (recurrent or intermittent ischemic)\(^{5}\). The low-flow or ischemic form is painful and is the commonest type of priapism (95\%)\(^{4}\). High-flow or non-ischemic priapism is rare, painless and is commonly associated with pelvic, perineal or direct penile trauma due to injury to the cavernous artery\(^{6-9}\). Stuttering priapism is ischemic in nature associated with multiple recurrent intermittent self-limiting episodes of persistent erection usually lasting less than 3–4 h and its commonest cause is sickle cell disease (SCD)\(^{5}\). Patients with SCD have an increased risk of low-flow and stuttering priapism, but high-flow priapism is relatively uncommon in these patients\(^{6}\).

We report a case of non-traumatic refractory high-flow priapism evolving from a stuttering low-flow priapism in a SCD patient. The patient was successfully treated by super-selective transcatheter embolization of the penile arteries with an autologous blood clot.

Case report
A 37-year-old patient, who was known to have SCD, glucose-6-phosphate dehydrogenase deficiency and hypertension, presented with priapism. Initially, he developed self-limiting intermittent episodes of sustained erection without sexual excitation for 3 months. Each episode lasted for less than 2 h. Eventually he presented with a sustained erection for 12 days duration in another facility, where he received treatment for low-flow priapism by repeated corporal aspirations and transfusion of 3 units of blood with no detumescence. He was then referred to our hospital with refractory priapism associated with SCD.

The patient’s blood results revealed a hemoglobin level of 8.9 g/dl (normal, 14–18 g/dl), with 94.7% hemoglobin S. The patient was treated with intravenous hydration and alkalization, nasal oxygen and exchange transfusion. Aspiration of the corpora revealed bright red blood. The patient did not have any significant penile pain at any stage. Color Doppler ultrasound imaging demonstrated a marked increase in the flow of the penile arteries. There were no features of arterio-cavernous fistula or pseudoaneurysm.

After discussing the possibility of impotence, the patient agreed for selective embolotherapy. Following the obtaining of written informed consent, pelvic digital subtraction angiography was performed via a right transfemoral artery approach. A 5 French vascular access sheath was placed in the right common femoral artery and a 5 French C2 catheter was engaged in the right internal iliac artery. A 2.4 French microcatheter was advanced coaxially into the ipsilateral internal pudendal artery, which was embolized with an autologous blood clot (Figure 1 and Figure 2). The C2 catheter was then engaged in to the contralateral left internal iliac artery using the cross-over technique and the left internal pudendal artery was embolized with an autologous blood clot after selective catheterization with a microcatheter (Figure 3 and Figure 4).
priapism into ischemic and non-ischemic types for its appropriate management. In the ischemic form of the priapism, fully rigid corpora cavernosa; relative sparing or little involvement of the corpus spongiosum and glans penis; hypoxic and dark aspirated corporal blood; and absent or minimal arterial blood flow are seen\[^{10}\]. In the non-ischemic type, the corpora cavernosa are not fully rigid, the aspirated corporal blood is bright red without hypoxia or acidosis and is associated with increased blood flow, arteriolar–sinusoidal fistula or pseudoaneurysm\[^{10}\]. Doppler ultrasound study of penile arteries can be helpful in cases with equivocal clinical findings, where mean and peak systolic velocities can differentiate between ischemic and non-ischemic forms\[^{11}\].

Low-flow priapism is initially managed with intravenous hydration, alkalization, analgesia and exchange transfusion\[^{4}\]. However, if priapism persists, further treatment includes corporeal blood aspiration, irrigation with non-heparinized saline and intracorporeal administration of alpha-adrenergic agonists (sympathomimetic agents such as phenylephrine)\[^{4}\]. The surgical shunt procedure is the last resort when all attempts of other nonsurgical treatment options have failed\[^{12}\]. The initial management of high-flow priapism is observation and two-thirds of high-flow priapism patients resolve spontaneously during observation\[^{13,14}\]. In the rest of the patients with high-flow priapism, embolotherapy is a frequent treatment option, which can be performed in a number of way, including by use of autologous blood clot, gel foam, platinum microcoils or acrylic glue\[^{15-17}\]. Complications of embolization can include permanent erectile dysfunction, penile gangrene, inadvertent migration of the embolization material into other regional arteries, gluteal ischemia and perineal abscesses\[^{19}\]. Autologous blood clot embolotherapy has been reported in post-traumatic high-flow priapism patients\[^{19}\]. In our case, after the failure of initial management by corporeal aspiration, the non-traumatic high-flow state was successfully treated using autologous blood clot embolotherapy. The autologous blood clot and gelatin foam have transient effect as embolization agents\[^{10}\] and their use in high-flow priapism patients has the theoretical advantage of recanalization of penile arteries, as compared to platinum microcoils, to reduce the risk of permanent erectile dysfunction. Embolization can be repeated in cases of recurrence. If embolotherapy fails, surgical management is the last treatment option\[^{21}\].

**Conclusions**

Super selective embolization of unilateral or bilateral penile arteries with autologous blood clot is a relatively safe and effective non-surgical treatment option for high-flow priapism, even in patients with SCD and has a low risk of erectile dysfunction.

**Consent**

The patient provided written informed consent for the publication of this case report.

**Data availability**

All data underlying the results are available as part of the article and no additional source data are required.

I have reviewed the article and here are my comments:

This patient had the wrong diagnosis made and potentially could have had a disastrous complication of penile gangrene.

The diagnosis was ischaemic priapism of 12 days and the initial treatment was correct but deemed a failure.

After aspiration in this context a hyperdynamic flow occurs due to a reactive hyperaemia with reperfusion.

The Doppler performed after aspiration therefore records a high flow whereas the perfusion within the small vessels and tissues is absent and is necrotic and later fibroses down.

To then embolise a penis that already has necrotic tissue is dangerous.

This patient did not have high flow priapism.

Is the background of the case’s history and progression described in sufficient detail?  
No

Are enough details provided of any physical examination and diagnostic tests, treatment given and outcomes?  
Partly

Is sufficient discussion included of the importance of the findings and their relevance to future understanding of disease processes, diagnosis or treatment?  
No

Is the case presented with sufficient detail to be useful for other practitioners?  
No

Competing Interests: No competing interests were disclosed.
I have read this submission. I believe that I have an appropriate level of expertise to state that I do not consider it to be of an acceptable scientific standard, for reasons outlined above.

You provide an intriguing report and suggest a new treatment consideration for priapism. This specifically applies to the patient who has non-traumatic refractory high-flow priapism that apparently has evolved from a low-flow state in a sickle cell disease patient. Your success is applauded. There are some questions.

1. Some important data would be helpful to include to convince the reader about your findings. For instance, do you have the data for arterial blood gas measurement from the penis with blood aspiration that correlates with your observation of bright red blood? What were the color Doppler ultrasound imaging parameters that are increased? What were the reduced blood flow parameters after treatment? Perhaps a simple table of before and after blood flow parameters by the ultrasound technique would be very helpful for the reader.

2. A strong suggestion is to include arrows on your figures to show exactly where the embolization was performed. Legends for each figure can then specify the observation based on the location of the arrow.

3. Although this has been a successful technique, it is clear that it has a role specifically in this sort of patient only after high-flow priapism has been confirmed. This would not be a technique that would mistakenly be done for low-flow priapism. Otherwise, serious complications could be expected in the latter condition. It is suggested to the authors to emphasize this point strongly in your conclusion statement.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

The benefits of publishing with F1000Research:

- Your article is published within days, with no editorial bias
- You can publish traditional articles, null/negative results, case reports, data notes and more
- The peer review process is transparent and collaborative
- Your article is indexed in PubMed after passing peer review
- Dedicated customer support at every stage
