**Abstract**

The skin commensal *Propionibacterium acnes*, recently renamed *Cutibacterium acnes*, along with the other major pathophysiological factors of increased seborrhea, hyperkeratinization of the pilosebaceous unit, and inflammation, has long been implicated in the pathogenesis of acne. Recent advances have contributed to our understanding of the role of *P. acnes* in acne. Although there are no quantitative differences in *P. acnes* of the skin of patients with acne compared with controls, the *P. acnes* phylogenetic groups display distinct genetic and phenotypic characteristics, *P. acnes* biofilms are more frequent in acne, and different phylotypes may induce distinct immune responses in acne. *P. acnes* plays a further important role in the homeostasis of the skin’s microbiome, interacting with other cutaneous commensal or pathogenic microorganisms such as *Staphylococcus epidermidis*, *Streptococcus pyogenes*, and *Pseudomonas* species. In the era of increasing antimicrobial resistance, the selection of acne treatment targeting *P. acnes* and the prevention of antibiotic resistance play a key role in improving outcomes in acne patients and public health.

Any comments on the article can be found at the end of the article.
**Introduction**

The cutaneous microbiome exists in a finely tuned equilibrium in healthy skin that when perturbed may lead to various inflammatory skin diseases. The three most commonly observed cutaneous genera are *Corynebacteria*, *Propionibacteria*, and *Staphylococci*.

*Propionibacterium acnes* has been implicated in the pathophysiology of prostate cancer, sarcoidosis, infective endocarditis, infections involving prosthetic devices (such as prosthetic joints, central nervous system ventricular shunts, and cardiac implantable devices), and acne, the last of which is the focus of this review. *P. acnes* is a Gram-positive, non-spor-forming human skin commensal that prefers anaerobic growth conditions. It is a member of the normal skin microbiota along with *P. avidum*, *P. granulosum*, and *P. humerusii*. The *P. acnes* genome is 2.5 Mb in size and has been completely sequenced. It has genes encoding metabolic enzymes, enabling it to survive in microaerophilic conditions, but also lipases that degrade the lipids of the pilosebaceous follicle, providing the bacterium with the energy it needs. Recently, a taxonomic reclassification was proposed in which *P. acnes* was renamed *Cutibacterium acnes* to account for genomic adaptive changes and to differentiate it from other *Propionibacteria* species. In particular, specific lipase genes were identified encoding for triacylglycerol lipase and lysophospholipase able to degrade sebum lipids. However, it has been proposed that it is taxonomically valid to continue to use the genus name *Propionibacterium* for the cutaneous group within dermatology specialities for a range of different reasons, including to avoid confusion with the previous name, *Corynebacterium acnes*.

In this review, we describe the characteristics of *P. acnes* concerning taxonomy, the role of different phylotypes and *P. acnes* biofilm in acne pathophysiology, and the targeting of *P. acnes* with appropriate acne treatments and the respective implications in the homeostasis of the skin’s microbiome and the emergence of antimicrobial resistance.

**P. acnes taxonomy**

With regard to taxonomy, *P. acnes* has been classified into three phylotypes (phylogroups) based on gene sequences or biological characteristics (lipase activity): I, II, and III. These phylotypes in turn have been split into distinct subspecies known as *P. acnes* subsp. *acnes*, *P. acnes* subsp. *defendens*, and *P. acnes* subsp. *elongatum*, respectively, to denote distinct phylogenetic, genomic, and phenotypic characteristics as well as their association with different clinical diseases, including acne and progressive macular hypomelanosis.

The subspecies *P. acnes* subsp. *acnes* has been described. Extracellular enzymes include RNase, neuraminidase, hyaluronidase, acid phosphatase, lecithinase, and lipase. The bacterial cells ferment glucose, and lactic acid is produced from fermentable carbohydrates in variable quantities. The major long-chain fatty acid produced is 13-methyltetradecanoic acid. Gene sequence analysis of *P. acnes* on the basis of the genes *recA* and *tly* revealed further phylogenetic subdivisions within the type I clade: the types IA, IB, and IC. Higher-resolution methods provided additional differentiation of IA strains into types IA1 and IA2. *P. acnes* is subdivided into six phylotypes: IA1, IA2, IB, IC, II, and III. Multi-locus sequence typing and single-locus sequence typing (SLST) identified further subgroups among phylotypes, called clonal complexes.

The *P. acnes* phylgroups have been associated with specific diseases and distinct virulence, biochemical, and immunological characteristics that will be discussed in the following section.

**P. acnes in acne: the role of distinct phylotypes**

*P. acnes* has been regarded as an important member of the cutaneous microbiota. It has been linked to the inflammatory skin condition acne vulgaris for more than 100 years. The four major pathophysiological factors implicated in the pathogenesis of acne include the role of *P. acnes*, increased seborrhea, hyperkeratinization of the pilosebaceous unit, and inflammation.

*P. acnes* colonization of the skin is necessary but not sufficient for the establishment of acne pathology. *P. acnes* dominates the microbiota of pilosebaceous units and accounts for 87% of clones in patients with acne and in individuals without acne. *P. acnes* has been reported to represent more than 30% of the facial microbiota in patients with acne, but another study of 55 patients with facial acne reported lower rates (less than 2%) of sampled bacteria. These results should be interpreted with caution given the role of the sampling methodologies used. Different sampling methods, such as swab, scrape, cyanoacrylate gel biopsy, and needle biopsy, are used to collect skin bacteria for testing. Each technique targets different skin structures and anatomical sites. The sampling of superficial and intra-stratum corneum bacterial populations is considered quite straightforward. However, the sampling of hair follicle populations has proven more difficult and a skin biopsy may be required. The use of tape-stripping for hair follicle sampling in acne can be misleading, as multiple superficial and intra-stratum corneum microbial populations are sampled but bacteria may reside in a deeper part of the hair follicle. This area is inaccessible with the above-mentioned sampling methodologies, providing very little material from inside the hair follicle and making it difficult to standardize. *P. acnes* sampling with bacterial culture may not reliably distinguish between *P. acnes* populations with possibly variable pathogenic potential.

Although there is no quantitative difference of *P. acnes* in the skin of patients with acne compared with controls, its phylogenetic groups display distinct genetic and phenotypic characteristics in acne and different phylotypes are known to induce distinct immune responses in acne. Different *P. acnes* types have been isolated from acne vulgaris, and the type III strains have been associated with progressive macular hypomelanosis, underscoring the importance of genetic division of *P. acnes* and suggesting the involvement of specific *P. acnes* phylotypes in the pathophysiology of acne.

Focusing on acne, the typing of *P. acnes* isolates has revealed distinct profiles in patients with acne (Table 1).

Predominance of phylotypes
20
-  Phylotype IA1 the most dominant in patients with acne

of the extracellular polymeric substance (EPS) matrix of Propionibacterium acnes
In vitro growth of P. acnes biofilms demonstrated the composition of the extracellular polymeric substance (EPS) matrix of P. acnes biofilm with extracellular DNA, proteins, and glycosyl residues as well as upregulated mRNA expression of Christie–Atkins–Munch-Peterson (CAMP) factor 1. Only one study has investigated P. acnes biofilm in acne patients compared with controls. A case-control study showed that follicular P. acnes was more frequently demonstrated in samples from acne patients compared with matching controls. Furthermore, P. acnes from acne samples more frequently formed biofilms in the sebaceous follicles compared with control samples. Although similar biofilms have also been observed in skin diseases other than acne, such as folliculitis, folliculitis decalvans, and hidradenitis suppurativa, these were seen in terminal hair follicles.

The role of the P. acnes biofilm
Bacteria may exist as biofilms in their natural habitat. A biofilm is defined as a microbial aggregate embedded in extracellular matrix which protects cells from harmful conditions in the environment and facilitates escaping from host surveillance mechanisms. Burkhart and Burkhart (2007) suggested that P. acnes biofilm may penetrate into the sebum and act like an adhesive, leading to the increased cohesiveness of corneocytes and the formation of microcomedones. Additionally, a high availability of sebum, a nutritional substrate for P. acnes, may result in an increased proportion of metabolically active bacteria and contribute to a pro-inflammatory phenotype of the P. acnes biofilm. This may explain the acne flares in adolescence, when increased hormone and sebum production are dominant.

**In vitro growth of P. acnes biofilms** demonstrated the composition of the extracellular polymeric substance (EPS) matrix of P. acnes biofilm with extracellular DNA, proteins, and glycosyl residues as well as upregulated mRNA expression of Christie–Atkins–Munch-Peterson (CAMP) factor 1.

**Target activities of P. acnes in acne**
As P. acnes modulates the differentiation of keratinocytes and increases local inflammation, it is regarded as an etiological agent of both the microcomedone (a structure invisible to the naked eye) in the early stages of acne and of the inflammatory acne lesions. The different target activities of P. acnes in acne are summarized in Figure 1.

P. acnes shows complex interactions with key events implicated in the pathogenesis of acne. It interacts with the innate immunity, including Toll-like receptors (TLRs), antimicrobial peptides (AMPs), protease-activated receptors (PARs), and matrix metalloproteinase (MMP), and upregulates the secretion of pro-inflammatory cytokines, including interleukin-1a (IL-1α), IL-1β, IL-6, IL-8, IL-12, tumor necrosis factor-alpha (TNF-α), and granulocyte-macrophage colony-stimulating factor (GM-CSF), by human keratinocytes, sebocytes, and macrophages. Moreover, the production of AMP (IL-37, β-defensin 2), cytokines (IL-1α), and MMP was associated with the increased expression of AMP.
of the G-protein-coupled receptor PAR-2 in keratinocytes from acne-affected skin. P. acnes extracts are directly able to modulate the differentiation of keratinocytes by inducing β1, α3, α6, αvβ6 integrin expression, and filaggrin expression on keratinocytes, changes seen in the development of acne lesions. Interplay between P. acnes and macrophages in the perifollicular dermis can induce IL-1β, which in turn may further activate the NLRP3-inflammasome pathway in antigen-presenting cells and myeloid cells. Recent in vitro studies have revealed that P. acnes can induce IL-17 production by T cells (Th1/Th17)\(^{33}\). Clusters of CD3\(^+\) cells have been demonstrated in the vicinity of P. acnes-positive comedones, cells that are absent from the surrounding inflamed lesions. These findings in early acne stage further support the role of P. acnes in the initiation of inflammation\(^{15}\). P. acnes releases extracellular vesicles (EVs) which also induce cellular responses via TLR2 signal cascades. These P. acnes-derived EVs induce IL-8 and GM-CSF and decrease epidermal keratin-10 and desmocollin, contributing to the development of acne lesions\(^{35}\). Yu et al. showed that acne-associated P. acnes phylotypes induced distinct cytokine patterns in vitro in peripheral blood mononuclear cells from healthy individuals, including higher levels of inflammatory interferon-gamma (IFN-γ) and IL-17, suggesting a mechanism of inducing acne via both Th1 and Th17 pathways\(^{15}\). On the other hand, P. acnes phylotypes associated with healthy skin induced higher levels of IL-10. Moreover, there were different expression patterns between phylotypes; acne-associated phylotypes showed higher expression of an adhesion protein, whereas phylotypes associated with healthy skin showed higher expression of a cell surface hydrolase. These identified immune responses and proteomes of different P. acnes strains provided deeper insight into how specific P. acnes phylotypes influence the pathogenesis of acne\(^{12}\). In a follow-up study, Agak et al. reported differential effects of acne-affected skin- and healthy skin-associated lineages of P. acnes on CD4\(^+\) T-cell and Th17 cell responses and suggested that P. acnes strains express different antigenic components on their surface structure, possibly explaining the higher IL-17 levels induced in acne-affected skin-associated P. acnes strains\(^{36}\).

Furthermore, P. acnes has been implicated in lipogenesis and sebum production, as it stimulates the sebaceous glands and sebum synthesis via the corticotropin-releasing hormone (CRH)/CRH receptor pathway\(^{37}\). Expression of the complete CRH system has been described in acne; a study in biopsies from the facial skin of patients with acne reported a stronger expression of CRH in sebocytes of acne-involved skin compared with non-involved and normal skin\(^{38}\). In particular, CRH augments the synthesis of sebaceous lipids and induces IL-6 and IL-8 release by sebocytes, mediated by the CRH receptor\(^{39}\).

A recent study reported that a secretory CAMP factor of P. acnes has a role in its cytotoxicity, as mutations of CAMP diminished P. acnes colonization and inflammation in mice\(^{40}\). P. acnes CAMP factor can induce cell death of sebocytes in sebaceous glands, resulting in amplification of the inflammation response\(^{41}\). In addition, a study reported that the P. acnes surface protein CAMP factor 1 stimulated keratinocytes in vitro by interacting directly with TLR2\(^{42}\).

Porphyrins are secreted by P. acnes and can generate reactive oxygen species that induce inflammation in keratinocytes and result in acne lesions. Johnson et al. showed that acne-associated

---

Topical antibiotics, especially antibiotic susceptibility patterns showed in cutaneous samples that when strains with cross-resistance to different antibiotics. A difference in the α possible explanation is the fact that there are different phylotypes differ between patients with and without acne. Interestingly, antibiotic treatment for acne that decreases colonization of the skin with P. acnes species were cultured from the cheeks, but there was no effect in the autophagic activity of keratinocytes. On the other hand, P. acnes may limit the proliferation of S. aureus and S. pyogenes by promoting triglyceride hydrolysis and propionic acid secretion. As a result, an acidic pH is maintained in the pilosebaceous follicle. A change of the microbiome composition may lead to a disturbed skin barrier and inflammation. In acne, a modified profile of P. acnes is noticed; different phylotypes differ between patients with and without acne31. Hall et al. showed in cutaneous samples that when P. acnes was present, Pseudomonas species typically were not, and vice versa32. Interestingly, antibiotic treatment for acne that decreases P. acnes colonization on the skin may also result in Gram-negative folliculitis caused by Pseudomonas33. Megyeri et al. recently proposed that P. acnes strains may be implicated in antimicrobial defense pathways by triggering a local increase in the autophagic activity of keratinocytes34.

P. acnes resistance to antibiotics

The antibiotic resistance of P. acnes is a worldwide problem, and rates of resistance increased from 20% in 1979 to 64% in 2000; rates for tetracyclines were lower compared with rates for clindamycin and erythromycin35. A study of 664 patients in the UK, Spain, Italy, Greece, Sweden, and Hungary reported that the prevalence of P. acnes resistance rates ranged from 50.8% to 93.6% to any antibiotic (tetracycline, macrolide, lincosamide, and streptogramin B) and that all included dermatologists who specialized in treating acne were colonized with resistant Propionibacteria36.

A difference in the in vitro antibiotic susceptibility patterns of P. acnes among different countries is recognized37-40. A possible explanation is the fact that there are different antibiotic-prescribing habits among the countries and even different concomitant topical agents used. In studies from Korea, the UK, Colombia, Mexico, Hong Kong, Hungary, and Spain, P. acnes antibiotic resistance was noted in 36.7%, 55.5%, 40%, 75.5%, 54.7%, 51%, and 94% of patients with acne, respectively (Table 2)37.

Macrolide-resistant P. acnes is frequently isolated from patients with acne vulgaris, and the majority of resistant isolates have the 23S rRNA mutation38. Long-term, low-concentration exposure to macrolides increased the resistance of P. acnes39.

Implications of antimicrobial resistance

The effect of acne treatments may be influenced by the presence of antibiotic-resistant P. acnes41. The widespread use of antibiotics to treat acne may result in the development of P. acnes strains with cross-resistance to different antibiotics and have possible implications in acne and other diseases where P. acnes may be the causative pathogen41.

Given the frequent use of antibiotics for acne treatment, recommendations on acne treatments aim to limit the risk of antimicrobial resistance of P. acnes and other bacteria42-45. As a general rule, the long-term use of topical antibiotics in monotherapies should be avoided, as they may lead to an increase in antibiotic-resistant P. acnes46. Antibiotics are not indicated for predominantly comedonal facial acne (Figure 2). Topical antibiotics, especially as a fixed combination with benzyl peroxide (BPO) or retinoid, may be indicated for predominantly papulopustular inflammatory facial acne. Topical fixed-dose combination treatments present the advantage of a quicker onset of action and may limit the risk of antimicrobial resistance associated with antibiotic monotherapy. If the use of topical antibiotics is indicated, BPO or a topical retinoid should be added with the aim to reduce the risk of antimicrobial resistance46,47. Topical antibiotics are not suitable for maintenance acne therapy; instead, topical retinoids are preferred, and BPO is added for an antimicrobial effect if needed. BPO further exhibits antimicrobial activity against P. acnes. Azelaic acid inhibits the synthesis of cellular protein in aerobic and anaerobic microorganisms, such as P. acnes, and does not induce bacterial resistance48.

Systemic antibiotics for acne, in combination with a topical agent (BPO, retinoid, or azelaic acid), are indicated for moderate to severe inflammatory papulopustular acne and acne affecting the trunk (Figure 3). The duration of the oral antibiotic regimen should not exceed 3 months. Oral tetracyclines (doxycycline or lymecycline) are the antibiotic of first choice for acne when a systemic antibiotic is considered49,50,51. Treatment with oral macrolides should be avoided because of high rates of antimicrobial resistance reported for P. acnes worldwide52.

A study of 56 patients with cystic or severe acne vulgaris treated with oral isotretinoin (1 mg/kg per day) reported that the colonization of the skin with P. acnes was modified; oral isotretinoin, though not an antibiotic, correlated with a reduction in the numbers of P. acnes, including isolates resistant to antibiotics, that were cultured from the cheeks, but there was no effect in P. acnes sampled from other anatomic sites57.

Emerging off-label therapeutic modalities for acne, such as topical photodynamic therapy (PDT) with photoactivation of aminolaevulinic acid (ALA) or methyl aminolaevulinic acid (MAL), target *P. acnes*, underlying its role in the pathogenesis of acne\(^6\). The mode of action of PDT includes not only photodynamic damage of the sebaceous gland but also the photodestruction of *P. acnes*\(^6,7\).

The potential for vaccination against *P. acnes* was investigated, and relevant studies initially stopped in 2011, as effectiveness in humans with acne was not shown\(^7\). Interestingly, a recent study reported the efficacy of CAMP factor antibodies in the neutralization of the acne inflammatory response in *ex vivo* acne models; the incubation of *ex vivo* acne skin explants from acne patients with monoclonal antibodies (mAbs) to the *P. acnes*-secreted
CAMP factor diminished the amounts of pro-inflammatory cytokines IL-8 and IL-1β. The authors also proposed that the injection of the mAb to CAMP factor directly into acne lesions may prove to be beneficial.

Conclusions
Significant progress has been made in understanding the role of *P. acnes* in the pathogenesis of acne. Although there is no quantitative difference of *P. acnes* among patients with acne and healthy individuals, *P. acnes* phylogenic groups may display distinct genetic and phenotypic characteristics. Different phylotypes may induce distinct immune responses, and the *P. acnes* biofilm has been reported more frequently in patients with acne. Furthermore, *P. acnes* plays important roles in the homeostasis of the skin’s microbiome, interacting with other cutaneous microorganisms such as *S. epidermidis*, *S. pyogenes*, and *Pseudomonas* species. Non-antibiotic approaches targeting *P. acnes* without inducing antibiotic resistance may improve patient outcomes in acne while avoiding public health issues.

Open Peer Review

Current Peer Review Status: ✓ ✓

Editorial Note on the Review Process
F1000 Faculty Reviews are commissioned from members of the prestigious F1000 Faculty and are edited as a service to readers. In order to make these reviews as comprehensive and accessible as possible, the reviewers provide input before publication and only the final, revised version is published. The reviewers who approved the final version are listed with their names and affiliations but without their reports on earlier versions (any comments will already have been addressed in the published version).

The reviewers who approved this article are:

Version 1

1 Andrew McDowell
Northern Ireland Centre for Stratified Medicine, Biomedical Sciences Research Institute, Altnagelvin Area Hospital, University of Ulster, Londonderry, UK

Competing Interests: No competing interests were disclosed.

2 Christine Roques
Laboratoire de Génie Chimique, Faculty of Pharmacy, Université de Toulouse, Université Paul Sabatier, Toulouse, France

Competing Interests: No competing interests were disclosed.

The benefits of publishing with F1000Research:

- Your article is published within days, with no editorial bias
- You can publish traditional articles, null/negative results, case reports, data notes and more
- The peer review process is transparent and collaborative
- Your article is indexed in PubMed after passing peer review
- Dedicated customer support at every stage
