Oral Biology and Oral Science Research Center Faculty of Dentistry, Universitas Indonesia, Jakarta, 10430, Indonesia

Abstract

**Background:** The aim of this study was to analyze the synergistic relationship between *Candida albicans* and *Streptococcus mutans* in children with early childhood caries (ECC) experience.

**Methods:** Dental plaque and unstimulated saliva samples were taken from 30 subjects aged 3-5 years old, half with (n=15, dmft > 4) and half without (n=15) ECC. The abundance of *C. albicans* and *S. mutans* and relative to total bacteria load were quantified by real-time PCR (qPCR). This method was also employed to investigate the mRNA expression of glycosyltransferase (gtfB) gene in dental plaque. Student’s t-test and Pearson’s correlation were used to perform statistical analysis.

**Results:** Within the ECC group, the quantity of both microorganisms were higher in the saliva than in dental plaque. The ratio of *C. albicans* to total bacteria was higher in saliva than in plaque samples (p < 0.05). We observed the opposite for *S. mutans* (p < 0.05). The different value of *C. albicans* and *S. mutans* in saliva was positively correlated, and negatively correlated in dental plaque. Transcription level of *S. mutans* gtfB showed a positive correlation with *C. albicans* concentration in dental plaque.

**Conclusion:** *C. albicans* has a positive correlation with cariogenic traits of *S. mutans* in ECC-related biofilm of young children.

Introduction

Early childhood caries (ECC) remain the most common childhood oral health problem, globally\textsuperscript{1}, and Streptococcus mutans has been known for its important role in ECC development\textsuperscript{2}. However, in recent years, Candida albicans has frequently been linked with its synergistic relationship with S. mutans in dental plaque recovered from children with ECC\textsuperscript{3,4}. Consequently, many studies using different methods have been conducted to identify, quantify, and explored the relationship of this fungus with S. mutans\textsuperscript{5,6}. However, a controversial report does exist, where C. albicans tends to decrease the cariogenic traits of S. mutans in \textit{in vitro} dual-species biofilm\textsuperscript{7}. Therefore, the main purpose of this study was to validate the synergistic relationships between C. albicans and S. mutans, when growing in caries-related biofilm. For this reason, we required preschool children with ECC experience, and we used qPCR since it is practice and reliable as a quantitative molecular tool of clinical oral samples\textsuperscript{8}. The fungus and bacterium concentrations in saliva sample were used as control, and we compared the outcomes with those subjects noted as children with free caries (FC).

Methods

Subjects

Oral samples were collected from 30 required preschool children (male and female, 3–5 years old), in two different locations located near (about 30 km) to Jakarta, the capital city of Indonesia. The diagnostic of ECC referred to the criteria provided by the American Academy of Pediatric Dentistry, as previously reported\textsuperscript{9}. The preschool children were recruited to get 15 subjects for each group. Thus, in this study, children were categorized into two different groups; children without any history of caries, including white-spot lesions, (caries free; CF group) and ECC group with decay-missing-filled teeth (dmft) index >4. To be included as subjects in this study, the children were required to be free of symptomatic oral candidiasis, have the absence of any medication therapy during the one month before this study, and have not worn any intraoral appliances. Before oral samples collection, written permission (informed consent) for children to participate was obtained from parents or guardians, according to the guidance provided by the Ethics Committee of Faculty of Dentistry, Universitas Indonesia.

Saliva and plaque samples were immediately cold-transported to the laboratory. For saliva samples, after centrifugation, the sediments were washed three times with 0.5 ml sterile milliQ water between each centrifugation and kept in -80°C until use. Similarly, plaque samples from caries-free or those with ECC were cold-transported to the laboratory and processed as mentioned above, then stored at -80°C until use.

Quantification of \textit{C. albicans}, \textit{S. mutans}, and total bacteria by qPCR

Bacterial/fungal DNA was obtained by centrifugation each sample in the microtube, using Trizol reagent (Sigma-Aldrich, Dorset, UK). Extracted DNA sample was kept at -20°C after determining the concentration and the quality by Qubit assay reagents (Invitrogen, Carlsbad, CA). The genomic DNA samples were dissolved in Tris-EDTA (TE) buffer and kept in -20°C freeze until used. Further, the DNA samples were quantified through a qPCR reaction with universal primers for the 16S rRNA genes and \textit{C. albicans}/\textit{S. mutans}-specific primers as shown in Table 1. For PCR-quantification, each sample was run in triplicate on an ABI StepOnePlus Real-Time PCR System with SYBR Green PCR Master Mix (Applied Biosystems, Foster City, CA, USA) according to the manufacturer’s protocol.

The PCR conditions were run in a final reaction volume of 10 µl, composed of 50 ng of sample DNA and 1 µM of each

</table>
primer (Table 1), with thermal cycling condition consisted of a 10 min initial denaturation at 95°C, followed by 40 cycles of 95°C for 15 s and 65°C for 60 s. The cycle threshold (Ct) were determined automatically by the instrument, and a dissociation curve of the amplified fragment set as follow; 95°C for 15 s, 60°C for 60 s, and 95°C for 15 s.

Estimating the amount of genomic DNA of both microorganisms tested was determined by constructing standard curves with r² values for both organisms tested as well as total bacteria (Figure 1A–C). To do this, we used a 10-fold serial dilution of extracted fungal and bacterial genomic DNA from overnight cultured of C. albicans ATCC 10231, S. mutans Xc, and Escherichia coli JM 107, respectively. The number (CFU/ml) assessed by plating culture dilutions on sabouraud agar, tryptone-yeast extract cysteine with sucrose and bacitracin (TYCSB) agar and Luria Bertani (LB) broth for C. albicans16, S. mutans17, and E. coli18, respectively. The same strains were used as positive control for qPCR. Therefore, quantification of C. albicans and S. mutans from plaques and saliva achieved by plotting the Ct values against the log of the respective standard curve. In this study, the ratio of C. albicans or S. mutans in the microbial community, in each sample, was determined as each microorganism proportion to total bacteria.

For both C. albicans and S. mutans, the detection limit by qPCR method was determined according to the limit of quantification (LOQ), obtained by the highest dilution of the template of the standard curve. When the Ct value of samples was higher than the LOQ, they would be considered positive, but their melting curve profile should be the same as those of the standards included when running the qPCR.

qPCR analysis of S. mutans gtfB in dental plaque samples
RNA isolation, purification, and reverse transcription of cDNA were performed similarly those in the previous study19. Platinum SYBR Green qPCR SuperMix-UDG (Invitrogen Life Technologies, Carlsbad, CA, USA), passive reference (ROX, Invitrogen), and S. mutans gtfB primers (Table 1), as well as 1 µg of cDNA, were used to quantify the cDNA, and non-transcribed RNA samples were used as control for genomic DNA contamination. The qPCR reaction was run on a similar machine as stated above with cycling conditions consisted of a 10 min initial denaturation at 95°C followed by 40 PCR cycles of 15 s at 95°C, and 60°C for 1 min. The formula of fold change 2ΔΔCt was used to calculate S. mutans gtfB gene expression that was normalized to the 16S rRNA, a well-established housekeeping gene20, and gtfB expressed in dental plaque of FC group was set to be the control.

Statistical analysis
The variables for quantification, proportion, and the mean quantitative gene expression were assessed using Student’s t-test, while Pearson’s correlation two-tailed test was used to depict

![Figure 1. Standard curve construction and melting temperature of qPCR.](image-url)
a linear association. Microsoft Excel software was used to perform statistical analysis, and a p-value < 0.05 was considered significant.

Results

Quantitative levels of *C. albicans* and *S. mutans* and their proportion in saliva and dental plaque samples

Standard curves were used to determine the corresponding number of microorganism tested while melting peaks were used to assess the specificity of the amplicon using saliva and plaque samples (Figure 1D–F).

In general, this study showed that in all saliva and plaque samples, from either FC or ECC children, both *C. albicans* and *S. mutans* were present. The quantification (log DNA copies) and proportion (% to total bacteria) of *C. albicans* and *S. mutans* in saliva, as well as plaque samples, are presented in Figure 2. Comparatively, it was observed, in either sample tested, a significantly higher number of both microorganisms in ECC children was found more than in those of the FC children (p < 0.05). However, in either group, the quantitative level of *C. albicans*, in the saliva sample was found to be significantly lower than those of *S. mutans* (p < 0.05). When comparing plaque and saliva samples within ECC children, we observed that the load (log DNA copies) of either microorganism in plaque was significantly lower than that in saliva (p < 0.05, Figure 2A).

Furthermore, we compared the proportion of *C. albicans* and *S. mutans* DNA relative to total bacterial DNA in saliva and dental plaque samples, in FC and ECC children. Within ECC children, there was a significantly higher proportion ratio (Ca/Tb) of *C. albicans* in saliva samples (35.5%), than that in plaque samples (13.5%) (p < 0.05). For FC children the ratio was not statistically different (saliva, 8% and plaque, 5.3%) (Figure 2B).

Similar analysis was carried out for the *S. mutans* proportion ratio (Sm/Tb). The result showed a different trend, with a significantly higher proportion of *S. mutans* in plaque (99%) than that in the saliva (62%) of ECC children (Figure 2B). The result also showed the proportion of this bacterium to total bacteria in saliva and plaque samples showed a significant difference between ECC and FC children (p < 0.05). Interestingly, there was a trend within dental plaque sample in ECC children, *S. mutans* DNA increased most with increased of *C. albicans*’ DNA (Figure 2B).

Association between the value of *C. albicans* and *S. mutans* in dental plaque and saliva of ECC children

We further evaluated the possible linear relationship of *C. albicans* and *S. mutans* load or their proportion and ECC experience in the subjects. Pearson correlations coefficient analysis revealed that the association between the numbers of these two microorganisms in saliva was moderate positively significant (r = 0.1, p < 0.05). On the contrary, a weak negative not substantial (r = 0.03, p > 0.05) between the decreasing number of *C. albicans* and the quantity of *S. mutans* in plaque samples observed in the ECC group (Figure 3A and B).

Quantification of *gtfB* gene transcription and its correlation with *C. albicans* and *S. mutans* amount in dental plaque

To confirm all the above results, we selected the *gtfB* gene, which has been reported to be mostly involved in the synergistic relationship between *C. albicans* and *S. mutans* in biofilm development, and compared its expression in each dental plaque of children tested. The qPCR result showed that level of mRNA *gtfB* was induced approximately 4.5-fold in ECC-derived dental plaque samples, and it was a significant difference compared to transcription level of *gtfB* mRNA in dental plaque sampled from children with FC (p < 0.05) (Figure 4A). Also,
Figure 3. Correlation between C. albicans and S. mutans loads in saliva (A) and in dental plaque (B), in the same subjects. Each circle depicts the value of C. albicans (Y-axis) and S. mutans (X-axis) in log CFU/ml for each subject.

gtfB transcription levels and the amount of C. albicans and S. mutans (CFU/ml) in dental plaque of children with ECC showed moderate ($r = 0.2$) and strong ($r = 0.9$) positive correlations, respectively, which was statistically significant ($p< 0.05$, Figure 3B and C).

Data are grouped according to the figure with which they are associated.
Discussion
Numerous studies have supported the idea that ECC may be better understood by focusing on the effect of the functional relationship between species within consortia instead of individual pathogens. This study focused on the relationship between C. albicans and S. mutans, as these oral microorganisms are frequently detected in the plaque of children with ECC. Since ECC may indicate a vast proliferation of the cariogenic microorganism, we sought to evaluate the extent to which the amount of C. albicans might correlate to the ECC experience. To do this, we used qPCR. This method enabled the quantification of the targeted microorganisms’ genomic DNA from oral samples. Thus, we examined the similarities and differences by comparing the amount and ratio to total bacteria of each microorganism in saliva and dental plaque samples, and verified their correlation with the occurrence of ECC. In general, we observed that the oral cavities of preschool children in this study, with or without ECC, are colonized by yeast (C. albicans) and bacteria, as represented by S. mutans. Overall, the fungus presence was always simultaneously detected with S. mutans, although children with ECC had a higher amount of C. albicans and S. mutans in their oral cavity, compared to those children with FC. As expected, in addition to saliva, these oral microbiotas commonly exist together in an ECC-related biofilm.

Our observation is in accordance with results from other studies, which found that in addition to S. mutans as a specific cariogenic bacterium, C. albicans can be part of the dental lesion. Moreover, previous studies showed strong synergism when C. albicans and S. mutans co-existed in biofilm, suggesting that this co-existence enhanced their virulence. However, our data showed, the fungus was detected at lower levels in dental plaque, compared to S. mutans. This support the previous in vitro study, found that the presence of C. albicans might favor the extensive colonization of S. mutans in dental biofilm.

The causes to generate site specificity bacteria proportion are believed to include local sucrose concentration in the oral cavity. In addition to sucrose, many factors may link to the presence of C. albicans in children oral cavity. These include infection at birth, baby’s feeding bottles, infected pacifiers, and carious teeth. We speculate that a high cariogenic diet might influence the interaction between C. albicans and S. mutans in these children tested. In turns, it becomes critical for ECC, since the presence of sucrose in the children oral cavity may lead to the ability of this species to grow within structured microbial biofilm. Further studies are therefore necessary.

The presence of yeast and bacteria is one of the local factors that contributes to the etiology of ECC. To obtain an overall insight into the impact of simultaneous participation of C. albicans and S. mutans when detecting together in each sample tested, we compared the percent proportion of C. albicans or S. mutans relative to total bacteria. As expected, the proportion of C. albicans was higher in saliva than in carious plaque among children with ECC. Other studies have reported this phenomenon, where Candida species were frequently isolated more, qualitatively and quantitatively, from saliva than from dental plaque and subgingival samples. During in saliva, this fungus might act as a bridge for oral bacteria to adhere to a mucosal surface, a mechanism that may protect this bacterium from being removed by salivary flow and swallowing. On the other side, biofilm formation is vital for C. albicans to survive as a pathogen, which involves attachment, colonization, and development of structural biofilm integrity composed of yeast and hypha. Our data illustrate that co-adhesion between C. albicans and S. mutans in cariogenic biofilm is one mechanism by which the fungus, in yeast form, survives in the oral cavity. Although the fungus morphology was not observed in this study, it has been reported by other studied that hypha morphology is not crucial for the C. albicans–S. mutans relationship when they grow in multispecies dental biofilms. Therefore, in addition to the morphology, both the number and proportion of salivary C. albicans influence the fungal–bacterial relationships, which further increases the risk of caries. Additionally, the flushing effect of saliva, as part of innate defense mechanism, might contribute to decrease Candida adherence to the oral surface, including tooth surface. Thus, the quality and quantity of saliva have an essential role in maintaining fungus behavior, as commensal or pathogen.

We observed that the proportion of S. mutans was higher in dental plaque than in saliva, and there was a tendency for the percentage of C. albicans to be lower in carious plaque, where the proportion of S. mutans increased. This observation indicates that S. mutans has an active role in orchestrating the development of cariogenic biofilms. This species has an essential part in attenuating the virulence of the fungus by interfering with the fungus transition, from yeast to hypha form when these oral microflora interact and grow in biofilm. This result further supported by the data of correlation analysis, in which the fungus-bacterium concentration in dental plaque sample showed a negative association, although a positive correlation was found in saliva sediment. This suggests that the ECC rate may not be connected to the quantity of C. albicans involves.

One of the mediators for the synergistic relationship between C. albicans and S. mutans is the streptococcal GtfB enzyme. Our finding indicates that cariogenic biofilm developed in ECC children accompanied by the increased transcription level of gtfB mRNA and enhance of S. mutans growth in dental plaque derived from children with ECC. In a clinical situation, this observation is relevant, since GtfB is the enzyme that synthesizes glucan polymers from sucrose. Thus, result of this study suggests that a high sucrose concentration, which is critical for the development of dental caries, might exist in the children oral cavity. Future studies are thus recommended.

Collectively, this study indicates that although the proportion of C. albicans was less in ECC-associated biofilm, it may support facilitation of a fungal-bacterial synergistic relationship. Yeast cells could be used by S. mutans to promote fitness and the bacterial survival, as shown by enhanced transcription level of gtfB, which reflects that more extracellular polysaccharides were produced to promote the fungal-bacterium relationship in caries-related biofilm.
The results of the present study cannot explain the reason for such an association. However, at least this study provides information on ECC experience among preschool children. The presence of C. albicans in dental plaque and saliva could be merely an indicator of oral health conditions and the high carbohydrate intake among the young children selected in this study, which might confer a survival advantage for C. albicans and it is favorable for ECC development. More studies are needed.

There is some limitation in this study. First, the primary disadvantage of qPCR used in this study is its inability to separate and quantify the viable from nonviable cells. This technique may result in false positives or an overly high estimation, as all DNA extracted from life or dead C. albicans, or S. mutans cell will be amplified. Since the number of viable cells is especially significant for diagnosing and monitoring disease, adding cell viability information to qPCR-based diagnostics should be considered. Second, the number of children involved in this study was small (15 subjects per group) because of difficulty in sample collection, primarily to obtain the plaque on the dentin surface.

Conclusions
This study shows that C. albicans contributes to increasing concentration of S. mutans by inducing the expression of gtfB mRNA in ECC-related biofilm. Therefore, results from this study would be useful as a starting point to consider C. albicans, as a potential target in prevention programs to reduce the high rates of ECC in individuals or groups of young children.

This paper reports an interesting and relevant study on ECC in children. The methods and contents of the papers are current, relevant and well-structured. However, some improvements could benefit the presentation including checking on grammar and typos, some revisions to sentence construction, highlights on the significance of this study, how the findings can be important to update of knowledge and current management of ECC, and comparison of data from Indonesia with other populations to perhaps illustrate novelty and significance to current available data.

Is the work clearly and accurately presented and does it cite the current literature?
Yes

Is the study design appropriate and is the work technically sound?
Yes

Are sufficient details of methods and analysis provided to allow replication by others?
Yes

If applicable, is the statistical analysis and its interpretation appropriate?
I cannot comment. A qualified statistician is required.

Are all the source data underlying the results available to ensure full reproducibility?
Yes

Are the conclusions drawn adequately supported by the results?
Partly

Competing Interests: No competing interests were disclosed.
I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Author Response 08 Nov 2018

Endang Bachtiar, Universitas Indonesia, Jakarta, Indonesia

Dear reviewer,

I am pleased to resubmit for publication the revised version of *Relationship between Candida albicans and Streptococcus mutans in early childhood caries, evaluated by quantitative PCR.*

We appreciate all the insightful comments provided by the reviewer. Based on the reviewer’s guidance, includes a number of positive changes, we endeavoured to improve the fit of the paper with the journal.

We hope that these revisions improve the paper such that the editor and reviewer now deem it worthy of publication in F1000 Research. Thank you for taking the time to help us improve the paper.

Sincerely,
Authors: Endang W Bachtiar and Boy M Bachtiar

Responses to reviewer #1:

We have fixed all grammar, typos, and some revisions to sentence construction. Furthermore all responses to the suggestions have been added in the manuscript in the yellow highlight sentences.

**Competing Interests:** No competing interests

Methods:
1. The authors did not mention how the examiners were calibrated, in order to reduce the inter- and intra-examiner variability when examining the preschool children, before grouping them into the early childhood caries and caries free groups.

2. The authors may have been able to collect more information on the oral hygiene habits or dietary intake of the subjects, before taking the oral samples.

Results:
1. In the caption for Figure 2, the symbol *p<0.05 should be indicated clearly. For Figure 2A, it is to show that there is a statistically-significant difference between the \textit{C. albicans} in saliva and dental plaque in the ECC group, and a statistically-significant difference between the \textit{S. mutans} in saliva and dental plaque in the ECC group. The use of top square bracket ( ) with an asterisk would be better to indicate which parameters are statistically compared.

2. For Figure 4A, the use of top square bracket ( ) with an asterisk would be better to indicate the parameters which are statistically compared.

Discussion:
1. In paragraphs 3 and 7, the authors speculated that a high cariogenic/high sucrose concentration diet might influence the interaction between \textit{C. albicans} and \textit{S. mutans} in the tested subjects. The authors may have been able to draw a better suggestion if the information on the oral hygiene habits or diet is obtained during the recruitment of the subjects (See my comment in Methods (2)).

2. In paragraphs 3, 7 and 9, the authors could have suggested what further studies are necessary to address the suggested theories/findings.

General comments:
1. The paper has a few grammar and language issues, in the Abstract and Methods sections.

**Is the work clearly and accurately presented and does it cite the current literature?**

Author’s response to reviewer comments

Comment provided by Reviewer #1

**Methods:**

Reviewer’s comment:

The authors did not mention how the examiners were calibrated, in order to reduce the inter- and intra-examiner variability when examining the preschool children, before grouping them into the early childhood caries and caries-free groups.

Author’s response:

We thank the reviewer for this correction. The problem has been fixed. As suggested by the reviewer, we have added sentence within material and method as follow: “two weeks prior to collect to clinical samples, the examiners were calibrated and trained by providing with the manual describing study protocol and guidance regarding the examination of preschool children. Therefore, only those trained-examiners evaluated the preschool children”.

Reviewer’s comment:

The authors may have been able to collect more information on the oral hygiene habits or dietary intake of the subjects, before taking the oral samples.

Author’s response:
In this study, we used a questionnaire regarding the parent’s/ guardian’s perception concerning children’s general and oral health, the risk factor for caries, dietary intake, and access to dental care. We noticed, in general, most of the responders believed that dental decay is a natural phenomenon. However, considering the complexity of the issue studied in this study, it is not the authors’ intent to include oral hygiene habits or dietary intake of the subjects (preschool children). Therefore, the related-data were not included in the current study.

Reviewer’s comment:

In the caption for Figure 2, the symbol *p<0.05 should be indicated clearly. For Figure 2A, it is to show that there is a statistically significant difference between the C. albicans in saliva and dental plaque in the ECC group, and a statistically significant difference between the S. mutans in saliva and dental plaque in the ECC group. The use of top square bracket ( ) with an asterisk would be better to indicate which parameters are statistically compared.

For Figure 4A, the use of top square bracket ( ) with an asterisk would be better to indicate the parameters which are statistically compared.

Author’s response:

According to the suggestions provided by Reviewer#1, we have corrected the old figures. The top square bracket has been added in Fig. 2A to indicate a statistically significant difference as suggested. For the Fig. 4A, we have added the top square bracket with an asterisk to indicate a significant difference between the parameters compared. Thank you.

Discussion:

Reviewer’s comment:

In paragraphs 3 and 7, the authors speculated that a high cariogenic/high sucrose concentration diet might influence the interaction between C. albicans and S. mutans in the tested subjects. The authors may have been able to draw a better suggestion if the information on the oral hygiene habits or diet is obtained during the recruitment of the subjects (See my comment in Method (2)).

Author’s response:

As mentioned above (response to the reviewer’s comment in methods (2)); it is not the authors’ intent to include the oral hygiene habits or diet of the preschool children in this study. This is because the information regarding oral hygiene habit or diet, provided by the accompanying guardian are difficult to be understood. Therefore, it is hard to interpret oral hygiene habit or diet data.

Reviewer’s comment:

In paragraphs 3, 7 and 9, the authors could have suggested what further studies are necessary to address the suggested theories/findings.

Author’s responses:
According to reviewer suggestion, we have added a better suggestion at the end of paragraph-3, as follow; “Further studies to obtain data regarding cariogenic diet are therefore necessary”. Additionally, we have added a sentence at the end of paragraph 7, as follow: “More studies regarding the involvement of gtfB expression, and how it relates to oral health conditions as well as cariogenic intake in Indonesian preschool children, are needed.

At the end of paragraph 9 (conclusion), as suggested by the reviewer, we added sentences; “Moreover, since the information regarding oral hygiene habit or diet, provided by the accompanying guardian are difficult to be understood, future studies involving preschool children may wish to involve examiners who are more experience in dealing with such parents/guardians when planning studies”. Thank you.

Dear Editor,
We are pleased to inform you that; 1/ for all the revision, as suggested by the reviewer, were showed in yellow-highlighting words, 2/ we revised the figure 2 and 4 to address the reviewer’s comments. Although the Fig. 3 is not included in reviewer’s comment, we revised the font, from the original (Arial) to new version (Times New Roman). Thus, all founds depicted in figures are similar. Thank you.
