Abstract

Background: Radiotherapy (RT) is indispensable in the treatment of head and neck cancer (HNC). Oral mucositis (OM) is a complication in HNC patients undergoing RT. This study aimed to identify the incidence, distribution of OM, and its effect on treatment breaks in a section of HNC in patients in Iraq.

Methods: This is an observational, descriptive cross-sectional study. In total, 50 patients with primary HNC, treated with external beam RT, from 30th April to 10th September 2017 at Baghdad Radiation Oncology and Nuclear Medicine Center were included in the study. Cases of OM were graded according to the World Health Organization scale.

Results: 80% of patients were below 65 years, and the male/female ratio was 2.6:1. Tumor sub-sites were nasopharynx (36%), larynx (22%), parotid (14%) and tongue (12%). 74% were smokers during or before starting RT. 86% were in stages III or IV. Incidence of OM was 72%; 16% grade I, 40% grade II, and 16% grade III. OM occurred in 93% females and 64% males, and 79% received concurrent regimens.

Conclusions: OM occurred in HNC treated by RT, more in females, who received chemotherapy plus RT, and those with tumors of the oral cavity and nasopharynx. OM-related unplanned breaks may interrupt treatment schedule. HNC imposes a double burden in Iraq as it attacks a productive age group, and the vast majority of the patients included in this study were diagnosed in advanced stages.

First published: 14 Feb 2019, 8:179 (https://doi.org/10.12688/f1000research.17882.1)
Introduction
Globally, head and neck cancer (HNC) accounts for 550,000 cases and 380,000 deaths, annually. In the US, HNC accounts for 3% of cancers, and in Europe, it was estimated to be 4% in 2012. Men are affected more than women with a ratio of 2:1 and 4:1 for US and Europe, respectively. In Iraq, the incidence of HNC is <2%. The primary causes of HNC are tobacco and alcohol, and viral infections including Epstein-Barr virus and hepatitis virus.

Radiotherapy (RT) plays a central and evolving role in the treatment of HNC and is used with or without chemotherapy (CT) as a definitive or adjuvant treatment. The oral cavity is susceptible to direct and indirect toxic effects of cancer CT and RT. This risk reflects high rates of cellular turnover for the lining mucosa, a diverse and complex micro-flora, and trauma to oral tissues during normal oral function. Oral mucositis (OM) is a debilitating side effect of RT and is exacerbated by concomitant CT, which can begin 1–2 weeks after initiation of RT as asymptomatic erythema often progressing to erosion and ulceration. The ulcers are painful, covered by a white fibrinous pseudo-membrane, associated with dysphagia and decreased oral intake.

Radiation therapy is an important method used in the treatment of head and neck cancers and, like all other methods used in treatment, it is not without the side effects of treatment. The injuries that occur to mucous membranes of the oral cavity are only part of those effects, which we can avoid and reduce them before and during and after treatment by adhering to the recommendations of the treating physician and the work of therapeutic planning. This study aimed to identify the incidence, distribution of OM, and its effect on treatment breaks in a section of HNC in patients in Iraq.

Methods
Study design and setting
This is an observational, cross-sectional study for HNC treated by external beam radiation therapy (EBRT), which included patients 50 patients, who were patients from 30th April to 10th September 2017.

The study was conducted at Baghdad radiation Oncology and Nuclear Medicine center, Bagdad, Iraq.

Participants
Patients who fit the eligibility criteria during the study dates who were scheduled for treatment were included in the study.

Dose of EBRT: 50-70 Gray, with a standard fractionation. Each fraction is 2Gy and 5 fractions per week. Radiation delivered with 3D conformal technique, using Elekta infinity, and Elekta synergy machines.

Eligibility criteria of patients was: primary HNC; T3 or T4 disease; positive nodes; residual disease; positive margins; perineural invasion; lymphovascular infiltration; extracapsular extension; treatment as described above.

Patients were excluded who had comorbid conditions, were treated in a palliative way, and those with metastasis or with a bad performance status.

Data collection
We conditionally collected data from patient files when they attended follow-up at the in-patient or/and out-patient clinic, or when these patients made visits to our center.

Variables collected:

Variables collected included: patient's gender, age and smoking status; tumor histopathology, stage, grade, subsites, and primary metastases; radiotherapy dose, fractions, interpretations and oral mucositis onset.

Assessment by World Health Organization’s scale of OM was performed as follows: Grade 0, no OM; Grade I, soreness; Grade II, erythema, ulcers, able to eat solids; Grade III, Ulcers, liquid diet only; Grade IV, alimentation not possible.

Statistical analysis
The collected data was categorized and analyzed by T-test to identify the incidence of OM and its distribution. SPSS IBM version 22 was used.

Ethical considerations
Written informed consent was obtained from the patients for the publication of their data in this article, and the study was conducted according to the ethical standards established by the 1964 Declaration of Helsinki. The Medical Ethical Committee of Baghdad University approved this study (code:611) on 18/04/2017.

Results
In the total patient population 72% were men, while 28% were women; male/female ratio was 2.5:1. The mean age was 53.3±11 years, and majority (38%) were between the ages of 55 and 64 years. Patients aged 65 years or more composed 20% of the total population. In total, 76% received CT before or concurrent with RT. The vast majority (86%) had advanced stages III or IV of cancer. 74% were smokers, during or before starting RT (Table 1); 86% of these were men, while 43% were women. Seven sub-sites were observed. The highest was the nasopharynx, followed by the larynx, parotid, and then the tongue (Figure 1).

In total 72% of patients had an incidence of OM, with no patients with grade IV; 40% were grade II, and grades I and III appeared in 16% of patients (Figure 2). OM occurred in 100% of young patients, below 35 years, 50% among 45–54 years old, and 90% in patients ≥ 65 years. 93% of women developed OM compared to 64% of men (Table 2). OM appeared in 50% of patients treated
with RT only, and 79% of those treated with concurrent protocols (Table 2). Grade III OM occurred in 18% of patients treated with RT and CT, while it occurred in 8% with RT only. OM appeared in 42% of patients with stage II cancer, and 77% and 75% of those with stages III and IV. OM occurred among 73% smokers and 69% nonsmokers. But severe OM (≥ grade III) occurred in 26% of smokers and 11% of non-smokers (Table 2). In this study, the majority of OM cases (47%) came from nasopharynx tumors (Table 2).

In total, 20% of patients had single breaks in their treatment schedule; the total break days was 20 days, giving an average of 2 days per break (Figure 3). Unplanned breaks were observed more in men, those who smoke, those with both RT and CT treatment, those with stage IV cancer, and those with grade III OM (Table 3).
Table 3. Distribution of unplanned breaks in treatment due to oral mucositis (OM) according to different variables in patients undergoing radiotherapy for head and neck cancer in Iraq (n=50). RT, radiotherapy; CT, chemotherapy.

Discussion

In most countries around the world, HNC is most common in men, and the male/female ratio ranges from 2:1 to 4:1\(^1\); in the UK, the ratio of male/female was 2.7:1, and in Australia it was 2.6:1\(^8\,10\). In our study the ratio was 2.6:1, which is consistent with studies elsewhere. In a similar study, Vera et al. found the mean age of 450 HNC patients was 61.3 ±12.3 years\(^14\), and it was 53.3 ±11 years in our study. According to Cancer Research UK, 50% of HNC cases each year are diagnosed in people aged 65 and over\(^14\). Some of our patients were aged 65 years but only constituted to 20% of the study population. This difference in age incidence can be attributed to many causes, such as the rising age incidence of HNC in the West\(^17\), higher life expectancy in those countries\(^3\), differences in environment, and differences in lifestyle\(^21\).

In the current study OM occurred in 72% of patients, while in other studies OM occurred among virtually all patients who are undergoing RT\(^11\,21\). Eilers and Million consider being female, young age and elderly as risk factors for developing OM\(^2\). This agrees with our study; 93% of females had OM, and there were high rates observed in the age groups of <35 years and >65 years.

In our study, grade III OM occurred in 18% treated with both therapies, while its appearance in 8% only among those who received RT only. Lalla et al. found a high incidence of OM with primary tumors in the oral cavity, oropharynx or in the nasopharynx\(^9\). This is well observed in the current study in which all patients had primary tumors. All patients with oral cavity, tongue, maxillary sinus and post-cricoid tumor developed OM. 94% of patients with nasopharynx tumor had OM and 47% were seen in nasopharynx patients. The tongue, oral cavity, and maxillary tumors constituted 36% of OM, while parotid tumor contribution was 11%.

The main principles of treatment by radiation is to deliver the total fractionated dose without interruptions. However, in daily clinical practice unplanned treatment interruptions are inevitable. Bese et al. concluded that patients, because of moderate or severe ulcerative OM had 15.8% and 46.8% incidences of RT break, respectively\(^23\). In our study, among 36 patients with OM, 10 of them (27.8%) needed breaks. The percent of breaks was high in males (35%), smokers (30%), those who were treated with CT plus RT (30%), those with stage IV (44%), and those with grade III OM (50%). In this study, two patients had breaks before the end of the 3rd week, and four had unplanned breaks at the 6th and 7th weeks, so a total of six patients (12%) had breaks at a critical treatment time. However, the break durations were only 1–3 days, but it is important to mention that in most of the times, the break is decided by patients themselves (subjective). It is convenient to mention here the conclusion of Bonomi et al., that OM is not only painful but also decreases the patient’s willingness to continue treatment\(^34\).

Conclusions

OM is an ongoing toxicity of RT, yet it still represents an important clinical challenge and causes burden to patients and caregivers. Most patients with HNC treated by radiation develop OM. The sub-site of the tumor is a main risk for development of OM. It was observed that young and old ages, combined RT plus CT, and advanced stage of tumor are associated with high incidence and severe OM. Patients with OM are at high risk of unplanned breaks in radiation. HNC in Iraq attack young and middle age people, which may lead to increases on its social and economic burden.

Recommendations

1. Using a multidisciplinary approach for oral management of HNC, before, during and after treatment.
2. Provision of psychological care and support services for these types of patients.
3. Education of patients and families regarding oral care.
4. Encouragement and support of multi-center studies and researches.
5. Raising competency of dentists, primary health care physicians and dermatologists to ensure early detection of HNC.

In this manuscript entitled “Oral mucositis in patients undergoing radiotherapy for head and neck cancer: An observational cross-sectional study”, the authors reported the cross-sectional analyses of oral mucositis of 50 head and neck cancer cases which had undergone radiation therapy. They presented 36 out of 50 cases (72%) manifested oral mucositis. Location of the tumor and gender were revealed to correlate the incidence of OM significantly, but no parameter was detected with significant difference regarding unplanned break of the therapy. The data and curation result have several matters to address.

Major points:
1. This manuscript shows limited impact of scientific novelty, nevertheless has a potent importance for indexing when considering the mean of regional statistical studies in Iraq.

2. The number of studied cases looks inadequate for the strength of statistical analyses. Even after the first publication in F1000 Research, the authors should make an effort to increase the number of analysed cases and revise the data. It might be expected that type of therapy should reveal a statistically significant difference in the incidence of OM.

3. Regarding the scoring system of OM, the authors employed WHO scale of OM only. This scale system should be simple and easy to value but there are more precise novel scoring systems such as Oral Mucositis Assessment Scale (Toro et al., 2007). The authors should at least refer to the OM assessment system in the discussion part.

4. In the method part, it looks inappropriate to test the significance using simple t-test in each parameter. At least, the authors should employ the multivariate analysis which might be available on SPSS software.

5. There was no presented data regarding the chemotherapy (type, timing, regimen as well as actual dose value). The authors should manifest the data and show the statistical analyses regarding this point.
6. Settings of the radiation therapy were not described in detail and also there was no data about surgery. If the patients got RT and chemotherapy only, the authors should describe it.

Minor points:
1. In the introduction part, the authors described Human Hepatitis Virus as a risk factor, but in the cited references, it looks like Human Papilloma Virus should be the risk factor.

2. Figure 1: The presentation of the pie chart looks unsuitable. Improvement of the colour usage (it’s not necessarily in colour figure) is recommended.

3. In the results (Table 2 and 3), it looks like smoking should be a big risk factor of incidence of HNC. The authors might be better to mention it more strongly.

4. Conclusion: It might be better to conclude in medical scientific terms.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to state that I do not consider it to be of an acceptable scientific standard, for reasons outlined above.
The authors report on the bone marrow changes during RT-CT in anal cancer patients as assessed by FDG-PET performed at week 2 of treatment. The study is of interest. Bone marrow sparing approaches tend to rely on the fact that bone marrow is a static organ at risk to be avoided during planning and delivery, but this is not the case, since both CT and RT may change the relative proportion of active/whole bone marrow and the spatial distribution.

I have some comments:

**Introduction:**
1. I would cite HPV infection as a risk factor.

**Methods:**
1. I would not call eligibility criteria out; it is a retrospective study and hence I would rather define patients' characteristics.

2. No data on chemotherapy are present (type, timing, regimen); please provide details.

3. With respect to RT, please provide details on the setting (definitive RT, adjuvant RT); if part of the cohort includes post-operative patients, please describe.

4. Which OM scoring scale did you use? Please specify.

**Results:**
1. Please provide data on the timing of worst OM; at which week of treatment.

**Discussion:**
1. Please cite and discuss Franco et al. (2017).^1

**General comment:**
1. I would suggest the authors to have their manuscript revised by a native speaker. Language needs to be improved.
