**Abstract**

We present a major public resource of mRNA splicing mutations validated according to multiple lines of evidence of abnormal gene expression. Likely mutations present in all tumor types reported in the Cancer Genome Atlas (TCGA) and the International Cancer Genome Consortium (ICGC) were identified based on the comparative strengths of splice sites in tumor versus normal genomes, and then validated by respectively comparing counts of splice junction spanning and abundance of transcript reads in RNA-Seq data from matched tissues and tumors lacking these mutations. The comprehensive resource features 341,486 of these validated mutations, the majority of which (69.9%) are not present in the Single Nucleotide Polymorphism Database (dbSNP 150). There are 131,347 unique mutations which weaken or abolish natural splice sites, and 222,071 mutations which strengthen cryptic splice sites (11,932 affect both simultaneously). 28,812 novel or rare flagged variants (with <1% population frequency in dbSNP) were observed in multiple tumor tissue types. Single variants or chromosome ranges can be queried using a Global Alliance for Genomics and Health (GA4GH)-compliant, web-based Beacon “Validated Splicing Mutations” either separately or in aggregate alongside other Beacons through the public Beacon Network, as well as through our website.

Amendments from Version 1

We updated Dataset 1 and the accompanying web resource, along with variant counts and statistics in the manuscript:

- We re-examined insertions and deletions (indels) with the new version of the Shannon pipeline (SP). Major updates to this version of SP include:
  - Binding sites adjacent to indels are now correctly localized.
  - Cryptic splice acceptor sites in the first exon and cryptic donor sites in the last exon of a gene are no longer reported.
  - Information models derived from splicing regulatory and transcription factor binding sites can now be utilized.
- Genomic and transcriptomic data from the International Cancer Genome Consortium (ICGC) became available to us in January 2019. This dataset was evaluated using the same methods as those used for TCGA.
- Differences in the expression of predicted mutant splice forms between two distinct BAM files were discovered from the same tumour of the same patient. We reanalyzed and replaced results for all variants in the TCGA-ESCA dataset using a second set of RNAseq BAM files.

DNAStack is acknowledged by including a citation of their recent article describing beacons.

We discuss:

- Comparison of results obtained from the TCGA and ICGC datasets. Figure 2 summarizes this.
- Comparison of gene expression values in patients with mutations validated by Veridical vs predicted mutations in the same gene that did not achieve statistical significance using this algorithm.
- Comparison of Veridical-flagged, cryptic splicing mutations with results of another study which evaluated cryptic splicing in TCGA (Jayasinghe et al., 2018).
- Evaluation of a large set of validated splicing mutations (n=1050, Cheung et al., 2019).

The analyses reported in this paper are being adopted by the genomics community. Since the version 1 publication (07 Dec 2018), the internet resource described has been queried by the global Beacon Network 6906 times and through the ValidSpliceMut website 8523 times.

See referee reports

Introduction

Next generation sequencing continues to reveal large numbers of novel variants whose impact cannot be interpreted from curated variant databases, or through reviews of peer-reviewed biomedical literature. This has created a largely unmet need for unequivocal sources of information regarding the molecular phenotypes and potential pathology of variants of unknown significance (VUS); in cancer genomes, such sources are critically needed to assist in distinguishing driver mutations from overwhelming numbers of bystander mutations. VUS classification criteria highlight the limitations in genome interpretation due to ambiguous variant interpretation. Of the 458,899 variant submissions in NCBI’s ClinVar database with clinical interpretations, nearly half (n=221,271) are VUS (as of November 5th 2018). Only 10,784 variants in ClinVar have been documented to affect mRNA splicing at splice donor or acceptor sites, with 1,063 of these being classified as VUS, and cryptic mRNA splicing mutations are not explicitly described. The current ACMG criteria for variant pathogenicity prevent clinical classification of most VUS. Functional evidence that VUS either disrupt or abolish expression of genes has been sought to improve classification and provide insight into the roles, if any, of individual VUS in predisposing or causing disease. We present a comprehensive data repository for a relatively common mutation type (cis-acting variants that alter mRNA splicing). Mutations are predicted with information theory-based analyses, and supported with functional evidence that variants in tumor genomes are specifically associated with abnormally spliced mRNAs that are infrequent or absent in transcriptomes lacking these variants.

Information theory (IT) has been proven to accurately predict impact of mutations on mRNA splicing, and has been used to interpret coding and non-coding mutations that alter mRNA splicing in both common and rare diseases. We have described an IT-based framework for the interpretation and prioritization of non-coding variants of uncertain significance, which has been validated in multiple studies involving novel variants in patients with history or predisposition to heritable breast and/or ovarian cancer.

The Cancer Genome Atlas (TCGA) Pan-Cancer Atlas (PCA) is a comprehensive integrated genomic and transcriptomic resource containing data from >10,000 tumors across 33 different tumor types. Here, we utilized IT-based tools for assessment of high quality sequenced variants in TCGA patients, as well as patients from tumor datasets provided by the International Cancer Genome Consortium (chronic lymphocytic leukemia, esophageal adenocarcinoma, malignant lymphoma, pancreatic cancer endocrine neoplasms, as well as liver, ovarian, and renal cell cancers), for their potential impact on mRNA splicing. The accuracy of predicted mutations was evaluated with the algorithm we previously developed that compares transcripts from individuals carrying these variants with others lacking them. The results of these genome-wide analyses are presented using an online internet resource, ValidSpliceMut, which can also be queried through the Beacon Network.

Methods

TCGA and ICGC data acquisition and processing

Controlled-access data was obtained with permission from the Data Access Committee at NIH for TCGA and from the International Cancer Genomics Consortium. Patient RNA sequencing BAM files (tumor and normal, when available) and their associated VCF files (GRCh37) were initially obtained from the CancerGenomeHub (CGhub). Files were later downloaded through Genomic Data Commons using the GDC Data Transfer Tool (version 1.3.0), as CGhub was decommissioned.
mid-project. Genomic data from ICGC was downloaded through the Score client (version 1.5.0). Variants in VCF files which did not pass quality control (QC) were not analyzed.

**Information analysis and RNA-Seq validation of splicing variants**

We used the Shannon Pipeline software (SP; which applies IT to rapidly perform high-throughput, in silico prediction of the impacts of variants on mRNA splicing)\(^{19}\) to analyze all QC-passing variants in VCFs from TCGA and ICGC (>168 million TCGA and >41 million ICGC variants) to evaluate their potential impact on splice site binding strength (changes in information content, \(R_i\) measured in bits). Variants which were predicted to strengthen known natural sites or weaken cryptic splice sites were excluded from all subsequent analyses. We also required novel cryptic splice sites to be strengthened by \(\geq 2\) bits (at least 4 fold), and with final strengths (\(R_{i,\text{final}}\) exceeding that of the nearest natural site of the same polarity.

To validate the potential impact of SP-flagged mutations, Veridical software analyzed genomic variants (including insertions and deletions) by comparing the RNA-Seq alignment in the region surrounding the variant with the corresponding interval in control transcriptomes (normal and tumor tissue of the same type) lacking the variant\(^{2,20}\). The Veridical algorithm: a) counts abnormally spliced reads in RNA-Seq data (categorized as either cryptic site use, exon skipping, or intron inclusion [containing or adjacent to the flagged mutation]), b) applies the Yeo-Johnson transformation to these results, and c) determines the null hypothesis probability (p-value) that the transformed read count corresponds to normal splicing. In tumor types where normal controls were not available, a set of RNA-Seq datasets from 100 different normal tissues from TCGA were used (e.g. a combination of 5 tissue types: BRCA, BLCA, LUAD, KIRC, PRAD). Veridical results that were not significant for a particular variant (p-value \(> 0.05\) for all evidence types, or evidence of altered splicing consisting of fewer than 2 reads) were not further analyzed. After this analysis, Veridical validated 341,486 unique mutations for their direct impact on mRNA splicing (Table 1). The Shannon pipeline-flagged and Veridical-filtered results were combined into a single large table (Dataset 1\(^{21}\)) that contains the source data for the ValidSpliceMut SQL database and the associated Beacon application.

**Development of the ValidSpliceMut database and Beacon**

We created a publicly accessible Application Programming Interface (API) (https://beacon.cytognomix.co) that can be utilized to programmatically query variants passing filter thresholds described above (Dataset 1\(^{21}\)). It was built in accordance with the GA4GH Beacon v1.0.0 specification, which describes a Representational State Transfer (REST) API for genetic data sharing\(^{22}\). A Beacon accepts queries using an HTTP request and returns JavaScript Object Notation (JSON). Our Beacon implementation is coded in PHP 7.0 and utilizes a MySQL database.

(version: 5.7.24) with indexes applied to variant ID, chromosome, and coordinate fields (GRCh37). The returned JSON object reports whether the variant was found within our Beacon dataset as well as metadata including splice site coordinate, splice type, site type, the IT-based measures \(R_{\text{mut}}\) and \(R_{\text{final}}\) affected individual IDs, tumor type, Veridical evidence by type annotated with significance level, and, if known, the corresponding rsID with its average heterozygosity (dbSNP 150). The metadata for each variant sent to the Beacon Network is a concise subset of available results in our database. It includes the first relevant database entry, meaning that if the variant exists within multiple individuals only the first will contribute fields to the metadata. However, among this metadata is a hyperlink to our local website containing results for any remaining tumors.

We developed the website, ValidSpliceMut (Figure 1) to serve as a local interface to our Beacon, allowing users to manually search for a variant, by gene name or genome coordinate range. ValidSpliceMut automatically queries our Beacon, and formats the results of the search, if any. This website provides a complete view of variants, including Veridical-based evidence on all data related to every affected individual. If a variant is associated with multiple splice sites, the user is presented with a brief overview of all affected sites and must select a desired site to continue. To obtain the coordinate of the queried variant in gene-centric notation, a link is provided which queries the Mutalyzer API and generates coordinates for all available transcripts. ValidSpliceMut only reports transcripts for the gene affected by the variant.

A results page presents variant-specific data in tabular format and an expandable list of panels describing the affected individuals. Each of these panels contains Veridical output in tabular format for the selected tumor, a link to the tumor metadata at US National Cancer Institute (by querying the GDC API to obtain a UUIID which is used to construct a link to the GDC data portal), an Integrative Genome Viewer (IGV) screenshot containing the variant (IGV screenshots are available for selected variants, see below), and a histogram which presents the expression levels of the variant-containing gene compared to all other gene expression levels across a selected normal tissue type (created dynamically using gnuplot 5.0). The tissue expression data is provided by GTEx (downloaded on 10/22/18). However, several tumor types did not have a GTEx equivalent (TCGA: CHOL, DLBC, MESO, READ, SARC, THYM and UVM; ICGC: MALY). The GNF Expression Atlas \(^2\) was downloaded from the UCSC Genome Browser and was used for expression data for both lymph nodes (DLBC; MALY) and the thymus (THYM). For the remaining tissues, expression data from the following studies were obtained from the Genome Expression Omnibus (GEO): GSE76297 (CHOL), GSE2549 (MESO), GSE15781 (READ) GSE44426 (SARC), and GSE44295 (UVM).

To generate IGV images presented on the webpage, a bash script was written to automatically load the RNA-Seq BAM file of a patient with a mutation of interest into IGV, set the viewing window within the region of interest (300nt window, centered on the variant), sorted to bring reads containing the variant of interest to the top of the screen (to increase chance of visualizing mutant splice form), followed by a screen capture. The generation and storage of IGV images for all patient-mutation pairs would be prohibitive due to limitations in time and server space requirements. Therefore IGV images showing evidence of splicing abnormalities were generated only for patient-mutation pairs which met the most stringent criteria: the mutation was required to be flagged for junction-spanning cryptic site use, exon skipping, or intron inclusion (with mutation); the flagged category must include 5 or more reads in this category; if the variant is present in the dbSNP database (release 150), the frequency was required to be < 1% of the population; and the Veridical results, in which the mutations flagged were required to exhibit p ≤ 0.01 for at least one form of evidence of a splicing abnormality. In some cases, the splicing event observed by Veridical may not be present within the image window as the automated procedure used to create these images does not present all evidential sequence reads due to limitations on the number of reads that are shown. Additionally, reads appearing as exon skipping may instead indicate a pre-existing cryptic site outside of the viewing window (for examples, see Table 2; FAT1: g.187521515C>A [c.11641-1G>T] and SMAD3:g.67482748C>G [c.1155-3C>G]).

**Dataset validation and discussion**

We have derived a GA4GH-standardized searchable resource for a large set of validated mRNA splicing mutations present in diverse tumor types. All variants passing QC in TCGA and ICGC cancer patients were analyzed with the Shannon pipeline\(^9\). This revealed that 1,094,749 variants were predicted to have significant impacts on normal mRNA splicing (380,852 natural and 752,472 cryptic splice sites; 38,575 affecting both types). Subsequent RNA-Seq analysis with Veridical\(^6\) provided evidence of abnormal gene expression specifically associated with a subset of these variant(s), identifying 341,486 unique mutations.

Our results contrast with an earlier TCGA study that investigated alternative mRNA splicing\(^6\) and demonstrated a limited set of non-constitutive exon-exon junctions attributable to cis-acting splicing mutations (n = 32). The 3,311 novel or rare variants from TCGA patients that we report specifically activate abnormal cryptic splicing (significant ‘junction-spanning cryptic site use’ reads found by Veridical). This exceeds the number reported in cited study that analyzed all available TCGA tumor transcriptionomes (n=1,914)\(^7\). When ICGC datasets were included, a total of 3,650 variants were found to activate cryptic splicing. Comparing the validated cryptic splicing mutations we found with this previous report\(^8\), 1,176 variants fulfilled our IT-based filtering criteria for constitutive splicing mutations. Veridical validated mRNA splicing effects for 824 of these variants (70.1%). The remaining 738 variants were reanalyzed for changes within the binding sites of regulatory splicing factors (SRF) that might affect normal mRNA processing. Together, including the effects on constitutive splicing, IT analysis of SRFs (SRSF1, SRSF2, SRSF5, SRSF6, hnRNPA1, ELAVL1, PTB and TIA1) cumulatively identified changes in binding strength in 1746 (91.2%) sites affected by these variants.
Figure 1. Screenshot of ATM:g.108214098G>T Results Provided By ValidSpliceMut Website. (A) The ‘Variant Position’ heading displays the variant of interest in g. notation, and provides a link which queries the Mutalyzer API to obtain the variant coordinate in a gene-centric c. mutation format. Variant-specific and splice site-specific tabular results are presented under the headings “Splice Site Information” and “Variant Data”. Results are organized by TCGA and ICGC sample IDs harboring the mutation within a series of expandable panels. A link is provided to patient tumor metadata on the GDC data portal. Each panel consists of read counts and p-values by Veridical evidence type. Significant p-values (≤ 0.05) are highlighted in bold. Evidence types deemed “strongly corroborating” (Viner et al. 2014) are color coded and correspond to the dynamically generated text appearing above the table. (B) An integrative genome viewer (IGV) image showing alignment of expressed sequence reads. IGV screenshots are provided only for mutations present <1% of population (in dbSNP 150), with ≥ 5 junction-spanning reads, and are highly significant (p < 0.01) for cryptic splicing, exon skipping, and/or intron inclusion with mutation. A specific IGV screenshot for this sample captures the region surrounding the mutation. Here, several RNA-Seq reads show skipping of the affected exon. (C) A dynamically generated histogram presents expression levels of all genes for a selected normal tissue type. Genes are grouped into bins based on expression level, denoted on the x-axis. The number of genes present in each bin is shown on the y-axis (log10 scale). The histogram key indicates the expression range of the variant-containing gene. Tissue type can be changed via a drop-down list.

</table>
Veridical validated splicing variants, which we define as mutations, were also tallied by tumor tissue type (Table 1). 38.5% of unique mutations in TCGA (n=131,347) significantly weaken natural splice sites, while 65.0% (n=222,071) strengthen novel or pre-existing cryptic sites. 238,570 of these mutations (69.9%) are absent from dbSNP 150. 72,615 mutations (21.3%) are rare (found in <1% of the population), of which 28,812 (and those not present in dbSNP) were detected in multiple tumor types and individuals. Valid mutations lacking rsIDs, by definition, represent either novel or recently observed variants. This low level of dbSNP saturation in TCGA is consistent with the possibility that many currently unknown mRNA splicing mutations may yet be discovered through additional sequencing studies.

The ValidSpliceMut database consists of variants from both TCGA and ICGC, however the vast majority of variants were sourced from TCGA (329,758 of 341,597 flagged, unique variants were found only in TCGA patients; 96.5%). This had been expected, as the ICGC datasets were smaller (492 patients with available RNAseq data analyzed across 7 tumor types). There were 7,380 Veridical-flagged ICGC variants that were absent from TCGA patients; 4,459 variants were flagged in both TCGA and ICGC datasets (of which, 287 were not found in dbSNP 150). To evaluate the frequency of flagged TCGA and ICGC variants, we compared those shared between the two datasets and present in at least 9 ICGC (left) and 24 TCGA (right) patients compared. A higher overall proportion of mutations are validated in the ICGC dataset (average of 38.6% for ICGC and 27.8% for TCGA). The dashed lines in each plot indicate the median (middle line), the upper and lower quartiles of the mutation fractions.

![Figure 2. Census of Recurrent Splicing Mutations Present in Multiple ICGC and TCGA Patients.](image)

*Figure 2. Census of Recurrent Splicing Mutations Present in Multiple ICGC and TCGA Patients.* Predicted splicing mutations present in multiple tumors from the same dataset that cause splicing abnormalities were analyzed to determine validation rates, since such variants were less subject to technical artifacts, such as sequencing errors. Violin plots indicate the distributions of the fraction of predicted and validated splicing mutations present in multiple patients relative to the total number of tumours carrying those mutations in the TCGA and ICGC datasets. To achieve statistical significance (95% C.I.), distributions of 1,379 validated variants shared by both datasets and present in at least 9 ICGC (left) and 24 TCGA (right) patients were compared. A higher overall proportion of mutations are validated in the ICGC dataset (average of 38.6% for ICGC and 27.8% for TCGA). The dashed lines in each plot indicate the median (middle line), the upper and lower quartiles of the mutation fractions.

SP-flagged variants). A higher percentage of ICGC variants compared to TCGA were confirmed with Veridical (49.1% to 30.9%, respectively), which may possibly be due to higher overall coverage in these regions in the RNAseq results for ICGC relative to TCGA. Interestingly, the fractions of novel variants i.e. not recorded in dbSNP, between TCGA and ICGC are inconsistent
(70.0% vs. 42.4%, respectively). We speculate that this may be related to differences in sequence coverage, since TCGA variants were identified from a mixture of whole genome (WGS) and exomes\textsuperscript{16}, while ICGC variants were exclusively derived by WGS.

To assess the predictive accuracy of SP, we also analyzed an independent set of experimentally-validated splicing mutations that altered exon definition (1,050 variants), originally sourced from the Genome Aggregation Database; gnomAD\textsuperscript{26} and validated with a high throughput, multiplexed splicing minigene reporter assay\textsuperscript{27}. Significant changes in constitutive splice site and/or (≥ 3 bit) SRF binding site strengths were found with SP for 1017 of these 1050 mutations (96.9%). Based on changes at constitutive splice sites alone, 447 variants were flagged (435 weaken natural sites, and 14 strengthen cryptic sites exceeding that of the most proximate natural splice site of the same polarity).

In Table 2, we highlight a representative subset of validated splicing mutations which were identified in known driver genes implicated in the COSMIC (Catalogue Of Somatic Mutations In Cancer) Cancer Gene Census catalog (CGC)\textsuperscript{30}. In total, 543 ‘Tier 1’ CGC genes exhibited at least one Veridical-flagged variant present in the ValidSpliceMut database. These mutations were associated with either increased exon skipping, intron inclusion, and/or cryptic site use. Mutations in Table 2 are hyperlinked to their corresponding ValidSpliceMut webpage, which provides additional information, including specific expression evidence for each of the tumors in the database that support predictions made by SP.

Many mutations generated multiple types of abnormal read evidence present in mis-spliced transcripts. Interestingly, a subset of TCGA mutations (n=33) produced evidence for every type of abnormal splicing reported by Veridical. Dataset 2\textsuperscript{29} (see Data Availability) describes 11 representative mutations that simultaneously increase exon skipping, intron inclusion, and activate (or significantly increase use of) a strengthened cryptic site. In all but one instance, the mutation weakens the natural site, while simultaneously strengthening an adjacent cryptic site. The only exception involves the gene SAP30BP, where simultaneously occurring mutations in the same read (in linkage disequilibrium; separated by 4 nucleotides) independently cause two separate splicing changes: g.73702087G>A (c.661-1G>A; abolishes the natural acceptor of exon 10) and g.73702091G>A (c.664G>A; creates a weak cryptic acceptor site). The combined splicing impact of these variants is significant exon skipping, intron inclusion, and use of the activated cryptic site.

This resource presents a set of splicing abnormalities in which we have the highest confidence because expression validation is required. We anticipate that some correct predictions of the Shannon pipeline may have not been validated by Veridical due to the limitations of mRNA detection; for example, either low expression of the gene harboring the mutation or nonsense-mediated decay of the corresponding transcript could be consistent with the effects of a valid splicing mutation, but in the absence of a sufficient number of abnormal reads, the mutation could not be confirmed. Indeed, expression of genes in tumors with validated splicing mutations exhibited greater overall gene expression than in other variants that were not validated in the same gene. The overall difference in gene expression between these two variant groups was statistically significant for 69.3% of genes based on the Student’s t-test (90% C.I.). Furthermore, overall gene expression in the group with Veridical-flagged variants exceeded the non-flagged group for nearly all other genes (99.7%). Differences between expression levels of Veridical-validated splicing mutations and other predicted mutations suggests the possibility that unverified SP predictions may arise from lack of or low levels of gene expression of the genes containing this subset of variants.

The original SP version that processed most of the TCGA data did not report regulatory splicing variants which influence exon definition. The Automated Splice Site and Exon Definition Analysis (ASSEDA) server\textsuperscript{1} analyzes individual variants for regulatory and constitutive IT changes. Due to time constraints, it was not feasible to perform a reanalysis with the upgraded SP of the entire set of ~209 million unique variants present in the TCGA and ICGC datasets. However, the SP upgrade did verify improvements in detection of both constitutive and regulatory splicing mutations using the set of validated mutations reported in a recent study\textsuperscript{29}. This version of SP (available through our MutationForecaster system) is capable of predicting mutations in splicing regulatory sequences at higher throughput than ASSEDA and, like ASSEDA, accounts for relative abundance of mRNA isoforms by exon definition.

The Validated Splicing Mutation resource should significantly contribute to reducing the number of outstanding VUS in tumor (and possibly some germline) genomes, and substantially increases the number of functional variants with previously unappreciated consequences to mRNA splicing, in particular, those which activate cryptic splice sites. In our earlier study\textsuperscript{29}, a subset of the TCGA breast cancer patient data was evaluated with IT-based tools, identifying 988 mutations as significantly altering normal splicing by Veridical (19% of total mutations flagged by IT). This database greatly expands the size of the repository. Here, a higher ratio of rare or novel mutations have been validated by Veridical (31% of total mutations were flagged by IT). The higher yields seen here could be related to mutations present in multiple samples from the same tumor type and other tumor tissues, which would be expected to increase the probability of observing abnormally expressed splice forms for the same mutation.

The manuscript by the Rogan group potentially provides an interesting resource. I would like to suggest to make it more accessible for the user, because in its current form it is very difficult to judge how reliable and strong the splicing predictions and RNAseq data in reality are. Our lab has checked some variants that are known to affect splicing, and it is very difficult to judge how this resource rates these. For example, Ri before and after mutation are difficult to interpret, it is unclear from this manuscript what these values in practice mean. The text in figure 1 that describes the reads under individuals (bottom of A) does not always correspond to the IGV screenshot in B. It is also unclear what figure C actually shows. The term anti-cryptic has not been defined. It is also not clear to me to what extent the predictions were confirmed for the entire set and whether certain types of predictions were more accurate than others. The resource may be very valuable, I would recommend to make it more accessible and understandable for the biological and diagnostic researcher, who could greatly benefit from it.

Is the rationale for creating the dataset(s) clearly described? 
Partly

Are the protocols appropriate and is the work technically sound? 
Partly

Are sufficient details of methods and materials provided to allow replication by others? 
Partly

Are the datasets clearly presented in a useable and accessible format? 
Partly

Competing Interests: No competing interests were disclosed.

Reviewer Expertise: Splicing
I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 23 Aug 2019

Peter Rogan, University of Western Ontario, London, Canada

Authors: We are grateful to the reviewer for these insightful comments, which we addressed below, in the manuscript and the ValidSpliceMut database.

Reviewer: The manuscript by the Rogan group potentially provides an interesting resource. I would like to suggest to make it more accessible for the user, because in its current form it is very difficult to judge how reliable and strong the splicing predictions and RNAseq data in reality are.

Response: To make this information more accessible to the user, we have made the following changes to the main text and to the ValidSpliceMut resource:

- Added a sentence which defines $R_i$ (see the next point)
- Added a "fold change" field to ValidSpliceMut, so users can understand how an information ($R_i$) change is related to splice site binding strength (originally defined in reference #9).
- Added a Glossary of terms to ValidSpliceMut containing all information theory-based terms ($R_i$, natural splicing) and Veridical terms (i.e. junction spanning, read abundance, etc) on the website, which were originally defined in the primary publication describing this algorithm and software (Viner et al., 2014).

The publication of the ACMG/AMP guidelines for interpretation of gene variants has accustomed users to simplified categorical characterizations, which has simplified clinical reporting. It should be recognized that a surprising number of variants in these databases have been reclassified recently, due to discordant interpretations and depositing of additional cases in ClinVar and other databases.

We have developed an algorithm which classifies the molecular phenotypes of the variants reported in our database. Note that we do not attempt to perform clinical classification, since the variants we analyzed cannot be definitively causatively linked to the cancer phenotypes of the tumours from which they were derived. Our algorithm performs evidence-based case classification (view additional Methods and the Figure 2 flowchart for details), with thresholds/cutoffs calibrated to the phenotypes reported in ClinVar database shared by ValidSpliceMut. There are three categories: 'aberrant', 'likely aberrant', or 'allele-specific alternative splicing'. This system is described in the manuscript in the ‘Methods’ section, and a categorical analysis of these classifications (i.e. proportion of natural site changes categorized as “aberrant”) are reported in the ‘Dataset validation and discussion’ section. We’ve updated Figure 1 to display the classification results using the same variant example in ValidSpliceMut that was shown in previous versions of this article.

In this version of the manuscript, we also have added an additional analysis of the control population gene expression in which alternate splicing was evident at the site of the mutation (however, these exomes lacked the variant itself). This involved the analysis of variants that did not pass Veridical-based filtering steps (i.e. were not statistically significant). This analysis (presented in the ‘Dataset validation and discussion’ section) was performed completely independently of the previously described, splicing molecular phenotype classification algorithm.
Reviewer: Our lab has checked some variants that are know to affect splicing, and it is very difficult to judge how this resource rates these. For example, Ri before and after mutation are difficult to interpret, it is unclear from this manuscript what these values in practice mean.

Response: We had not defined $R_i$ here, as it had been described in our prior publications which are cited. However, for completeness, we have added the following statement in the main manuscript: “$R_i$ is a measure of binding site strength; it is related to affinity through the second law of thermodynamics and is measured in bits (a glossary of IT and Veridical terms can be found here). According to Shannon information theory, only sites with $R_i$ values exceeding zero bits can be bound. The minimum fold change in affinity is exponentially related to the difference in $R_i$ values of wild type and mutant binding sites ($\geq 2^{\Delta R_i}$). For example, a 3 bit change would result in at least an 8-fold change in binding affinity.”

A glossary of terms to ValidSpliceMut has been included in the current version of the database to assist users in better understand the results of their queries. We also hyperlink to this glossary in the manuscript, where it is first mentioned.

Reviewer: The text in figure 1 that describes the reads under individuals (bottom of A) does not always correspond to the IGV screenshot in B.

Response: This discrepancy is due to a limitation on the number of reads which IGV can display at one time. This issue is most prevalent in regions of high coverage. While this is described in the main text, this explanation is given in the context of explaining why some IGV images may not display the splicing event at all.

“In some cases, the splicing event observed by Veridical may not be present within the image window as the automated procedure used to create these images does not present all evidential sequence reads due to limitations on the number of reads that are shown.”

This text has been edited to handle both instances where the IGV images is incomplete or absent:

“In some cases, the splicing event observed by Veridical may not be present (or displayed in its entirety) within the image window as the automated procedure used to create these images does not present all evidential sequence reads due to limitations on the number of reads that are shown.”

There are also cases where the user may observe more skipping reads than stated by Veridical. As mentioned in the manuscript, IGV images may include reads that appear to be exon skipping but are, in fact, activating cryptic splice site outside of the window range displayed. Although not explicitly mentioned, these false skipping reads could instead arise either from an alternate splice form that skips multiple exons or could be reads for a completely different gene overlapping the region. In these cases, Veridical will properly count only the reads skipping the exon of interest.

Reviewer: It is also unclear what figure C actually shows.

Response: The Tissue-specific Expression Histogram (Figure 1C) was included on ValidSpliceMut to allow the user to quickly determine the relative expression of variant-containing gene relative to
the overall gene expression corresponding to the normal tissue from which the tumour was derived. Expression levels are binned relative to all genes in the original dataset, and the bin containing the variant-containing gene is highlighted. This figure is relevant because the natural level of expressed at very low levels in a particular tumor type (or control tissue) may limit the number of reads observed, even if no mutation were present. A low basal level of expression impacts the confidence interval of the p-value reported by Veridical. The diagram in Figure 1C, for example, shows that ATM has a TPM (transcripts per kilobase millions) between 8-9 in mammary tissue (marked in purple; data from GTex), and that this particular range of expression is low to moderate compared to the rest of the breast transcriptome.

We have made slight adjustments to the Figure Legend:
“C) A dynamically generated histogram presents expression levels of all genes for a selected normal tissue type. Genes are grouped into bins based on expression level, denoted on the x-axis. The number of genes present in each bin is shown on the y-axis (log scale). The histogram key indicates the expression range which contains the variant-containing gene (purple). Tissue type can be changed via a drop-down list.”

Reviewer: The term anti-cryptic has not been defined.

Response: As this is a Data Note, we did not want to overexplain aspects of the Veridical software that had already been described elsewhere. As mentioned above, the manuscript cites the original Veridical paper (Viner et al., 2014), which defines this term:
- Cryptic site use/anti cryptic site use: “Equivalent to: cryptic corroborating / non-cryptic corroborating reads”
- Cryptic corroborating reads: “Reads occurring within the expected region for cryptic splicing to occurring (i.e. spliced-in regions). This region is between the variant splice site location and the adjacent (direction dependent) splice junction.”
- Non-cryptic corroborating reads: "Also termed "anti-cryptic" reads. Not within the expected region, but still within the portion that would be expected to be spliced out, had cryptic splicing occurred."

We also note that the Information icons (i) found next to each Veridical evidence-type in ValidSpliceMut direct the user to Viner et al. which define these terms. Finally, these terms are indicated in the aforementioned glossary on the ValidSpliceMut website.

Reviewer: It is also not clear to me to what extent the predictions were confirmed for the entire set and whether certain types of predictions were more accurate than others.

Response: In general, lower p-values indicate a high likelihood that the frequency of aberrant splicing reads is caused by the variant. A lower p-value means higher confidence, as would a higher total number of aberrant splicing reads used to compute said p-value. While we provide p-values for all evidence types examined by Veridical, Viner et al. (2014) suggests that junction-spanning cryptic site use, exon skipping, intron inclusion (with mutation) and read-abundance intron inclusion are the most powerful evidence of variant-directed, aberrant splicing:
"Not surprisingly, we have found that junction-spanning reads have the greatest value for corroborating cryptic splicing and exon skipping. Even a single such read is almost always sufficient to merit the validation of a variant, provided that sufficient control samples are used. For
intron inclusion, both junction-spanning and read-abundance-based reads are useful, and a variant can readily be validated with either, provided that the variant-containing experimental sample(s) show a statistically significant increase in the presence of either form of intron inclusion corroborating reads.”

**Reviewer:** The resource may be very valuable, I would recommend to make it more accessible and understandable for the biological and diagnostic researcher, who could greatly benefit from it.

**Response:** Thank you. We hope the improvements that we have incorporated in the article and the website have made the resource easier to understand and use.

**Competing Interests:** PKR cofounded and BCS is an employee of CytoGnomix Inc., which hosts the interactive webpage described in this study. CytoGnomix markets subscriptions to and services based on the software that generated the ValidSpliceMut database. EJM has no conflict of interest.

I approve the amendments from Version 1.

**Is the rationale for creating the dataset(s) clearly described?**
Partly

**Are the protocols appropriate and is the work technically sound?**
Partly

**Are sufficient details of methods and materials provided to allow replication by others?**
Partly

**Are the datasets clearly presented in a useable and accessible format?**
Partly

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** I have more than twenty years experience in the investigation of pre-mRNA splicing processes and especially their potential connection with a variety of human diseases, both monogenic
(Cystic Fibrosis, Pompe Disease, Neurofibromatosis) and polygenic (Amyotrophic Lateral Sclerosis, Frontotemporal Dementia). I am the author of more than 160 research papers in peer-reviewed publications and of several articles in scientific books on these subjects (orcid.org/0000-0002-1356-9074)

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.
discuss about the possible reasons of such a discrepancy. One of them is the possible occurrence of nonsense mediate decay which will not confirm the mutations because no or very few reads will be detected. However, as the authors acknowledge, the absence of supporting reads only in mutated individuals as compared to the presence of reads in WT sample would be a strong indication of the effective role of these mutations on splicing. This can be quantified from the same RNAseq data and in my opinion should be done.

5. In general, the authors seem to exclude that their prediction method could lead to false positives. Rather they justify the poor overlap with limitations of mRNA detection. If this is the case, this should be quantified and probably a comparison with other prediction methods could help.

6. Of the >351k mutations with an effect on splicing supported by RNA data, only 35 affect CGC genes. Is this only a subset of mutations affecting driver genes or is it the complete list? In the former case, I would suggest that the authors provide the full list as supplementary data. In the latter case, the authors should discuss the implication of such a low number. Considering that there are >700 CGC genes, does it mean that aberrant slicing is very rarely a driver event? Is the overwhelming majority of splicing variants passenger?

Is the rationale for creating the dataset(s) clearly described?
Yes

Are the protocols appropriate and is the work technically sound?
Partly

Are sufficient details of methods and materials provided to allow replication by others?
Yes

Are the datasets clearly presented in a useable and accessible format?
Yes

Competing Interests: No competing interests were disclosed.

Reviewer Expertise: Computational cancer genomics

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 07 Mar 2019

Peter Rogan, University of Western Ontario, London, Canada

We thank the reviewer for their valuable comments. Our responses follow:

1. The authors write that their IT-based framework to predict slicing variants "has been validated in multiple studies" and they refer to numerous papers. However, in all of them they act as co-authors, showing that their method is mostly used by themselves and their collaborators. This is not necessarily a problem, but it would certainly strengthen the study if the authors would perform a comparative assessment of their performance with other available methods to predict splicing mutations, for example those in dbNSFP. This will provide a less biased interpretation of the final results.
Response: We have previously compared our mutation prediction methods with others. Mucaki et al. Hum. Mut. 34:556-65 (2013) showed that IT-based single mutation and exon definition methods performed as well or better than MaxEntScan and Human Splice Finder websites. MaxEntScan computes relative entropy which is similar to IT, except it applies a correction for local base composition (which does not measure free energy, in contrast with IT: J. Theor. Biol. 201:87-92, 1989). Human Splice Finder does not measure changes in binding affinity and its basis is ad hoc. We also reviewed all articles (300+) which have used IT-based tools to predict changes in splicing (Caminsky et al., F1000Research 3:282, 2014). This reference covers the vast majority of studies that used IT-based bioinformatic tools for mutation analysis and, compared results obtained using these tools with other available software. The cited studies included a large proportion of mutations that we, ourselves, did not coauthor, or were analyzed by others, removing an obvious source of bias.

Regarding potential bias in our results, the IT-based position weight matrices (iPWMs) of splice recognition sites that we derived and use are based on a comprehensive set of splice sites spanning all known coding genes (see appendix of Rogan et al. Pharmacogenetics & Genomics 13(4):207-18, 2003). Other bioinformatic methods for splice site detection are based on many fewer splice sites for PWMs and are much more likely to be subject to bias based on how those sites were chosen. Also, the determination of information content in natural and mutated splice sites obeys the second law of thermodynamics (Schneider, J. Theor. Biol. 189:427-41, 1997); information contents have been formally proven to be related to binding affinities of splice site to splicesomes and splicing factors. MaxEntScan differs from IT because it applies a correction for local base composition, which is energetically and biochemically irrelevant to binding site affinity, and is therefore, biased.

As comparisons of IT with other methods have been covered previously, and the F1000Research Data Note article format is intended to specifically present results using the new resource we describe, in our opinion, reevaluation of other algorithms would not add anything of value to this manuscript.

2. Somehow related to the previous point, the authors mention that their results "contrast with another TCGA study that investigated alternative mRNA splicing". In my opinion this point should be further explored: what are the main differences and what is the extent of overlap in concordant predictions? What are the possible reasons for these differences? This is important because the cited paper in Cancer Cell analysed the same dataset of mutations.

Response: The paper being referred to in the reviewer's comment is Kahles et al., Cancer Cell., 34(2):211–224.e62018. This paper reports: “In a joint analysis of cis and trans associations with 50% prior on each type, we identified 32 cis- and seven trans-sQTL (Bonferroni corrected p < 0.05).” Information regarding these cis- sQTLs can be found here: [https://api.gdc.cancer.gov/data/3920a044-6874-4049-8010-55f0922243b7](https://api.gdc.cancer.gov/data/3920a044-6874-4049-8010-55f0922243b7).

However, the document that provided does not indicate that these are actual splicing mutations. The document contains SNP coordinates, but not sequence changes. An assessment of known rsIDs at these coordinates only accounted for only 7 of the variants in our database. In fact, none of the substitutions (nor the rsIDs) in the article could be related back to changes in mRNA splice strength. It is not possible to comparison the results presented in this paper to those in Kahles et al. (2018).
3. The authors notice that the number of variants which activate cryptic splicing exceed the number reported in a recently published study in Cell Reports. Similarly to before: what is the extent of overlap between the two datasets? Stating that a dataset is bigger than another one is not necessarily an indication that it is better.

Response: Jayasinghe et al. Cell Rep.;23(1):270-281.e3 (2018) identified 2056 variants in TCGA patients which activated cryptic splice sites, of which 1964 were confirmed by manual review of RNAseq data using the Integrated Genome Viewer (IGV). The data provided (Supplementary Table S1; “Passed Manual Review” tab) was sufficient to perform a comparison with our results. We scanned their manually reviewed variants using the Shannon Pipeline (SP). Despite reporting 1964 manually reviewed mutations, 50 mutations are shared between multiple patients (there are 1914 unique mutations total). 1510 of these mutations were found to alter at least one mRNA splice site (natural or cryptic), of which 1176 met our SP filtering criteria (either decreased natural site strength or cryptic splice sites strengthened by ≥2 bits and exceeding the strength of the nearest natural site of the same polarity).

We considered the possibility that splicing mutations in Jayasinghe et al. that were not flagged by SP could have instead altered the strength of splicing regulatory factor binding sites (SRFs). The high-throughput IT-based variant analysis tools needed to address this question were not available at the time the TCGA genomic data were processed. We recently introduced a new version of SP which is capable of analyzing variants impacting both constitutive splice sites and SRFs (including SRSF1, SRSF2, SRSF5, SRSF6, hnRNPA1, ELAVL1, PTB and TIA1). Upon analysis of the variants in Jayasinghe et al. for IT-derived changes in natural, cryptic and SRF binding site strengths, 1746 of the 1914 (91.2%) were found to be significant. It is conceivable that remaining unclassified variants may affect binding by splicing factors for which we have not yet derived iPWMs (i.e. SRSF7).

Of the 1176 variants meeting our filtering criteria, 824 were flagged by Veridical (70.1%). Interestingly, 27 Veridical-flagged mutations alter the same genomic coordinate in different tumours and another 64 affect the adjacent genomic coordinate within the same splice site in other individuals. We further investigated the remaining mutations (those evaluated, but not flagged) to better understand the discrepancy. In approximately 10% of cases, Veridical did not find any alternative validating cryptic splicing events in the region that contrasted with the read distribution in the set of control transcriptomes. For example, chr9:35389842G>C in TCGA-CN-5370 was expected to abolish the natural acceptor site of exon 24, however the read counts for intron inclusion in the RNAseq data were too sparse to be deemed significant (p=0.33).

Jayasinghe et al. also found mutations in TCGA patients that were not evaluated in our study. This could occur for either because the RNAseq BAM file for a particular TCGA patient failed to download, or the “key” file that associates the BAM file to its TCGA name was incomplete in some tumors (i.e. TCGA-CG-4436; TCGA-STAD), due to both the BAM file name and header lacking this information. This would not impact the accuracy of the data that is present in our database or that we report, only the level of concordance between our results and those of Jayasinghe et al.

When comparing this dataset with our own, we discovered an instance where discrepant RNAseq data for the same tumour in the same TCGA patient led to different IT results. Originally, Veridical did not find a significant splicing change in POLR1B exon 14 at the +1 position, a G>A mutation g.113331138G>A, present in patient TCGA-Z6-AAPN in the ESCA dataset. When we manually
reviewed the RNAseq BAM file used in this analysis, alternate or exon skipped splice forms were not observed, confirming the results reported from Veridical. In fact, TCGA deposited two separate BAM files containing RNAseq data for this same patient: "TCGA-Z6-AAPN-01A-11R-A406-31_rnaseq.bam" and "UNCID_2681450.b17c4505-8a84-4cdd-8782-lbc456deb2a6.sorted_genome_alignments.bam". The latter BAM file shows evidence of both predicted exon skipping and activation of a cryptic acceptor site 12 nt downstream of exon 14 of POLR1B. Comparison of SNPs between these BAM files in other genes did not show any evidence of sample switching or contamination. Although this issue does not appear to be widespread in the TCGA dataset, such discrepancies exceed the scope of our study, and rightfully should be addressed by TCGA.

Nevertheless, this discovery did prompt us to re-analyze the TCGA-ESCA variants through Veridical using the second set of BAM files, and we have now included those results to ValidSpliceMut. In this new set, the previously mentioned POLR1B mutation is deemed significant due to increased exon skipping (86 reads showing exon skipping; p=0.0000).

4. The authors validate ~27% of predicted splicing variants using the mRNA data (351k validated of the 1.2M predicted). This is a surprisingly low fraction. Later in the manuscript, the authors briefly discuss about the possible reasons of such a discrepancy. One of them is the possible occurrence of nonsense mediate decay which will not confirm the mutations because no or very few reads will be detected. However, as the authors acknowledge, the absence of supporting reads only in mutated individuals as compared to the presence of reads in WT sample would be a strong indication of the effective role of these mutations on splicing. This can be quantified from the same RNAseq data and in my opinion should be done.

In the revision of this paper, the fraction of validated predicted splicing variants in the ValidSpliceMut database increased from 27% to 31%, as a result of a series of improvements in the software used for processing. SP was significantly upgraded over the course of this project,. The previous iteration would incorrectly report information changes at pre-existing splice sites adjacent to certain mutations. These sites were characterized by genomic coordinates that were altered by insertions or deletions (indel), regardless of whether the site overlapped or included the sequence change. In such instances, some altered natural splice sites could be designated as cryptic sites. SP also reported changes at cryptic acceptor and donor sites in the first and last exons of a gene, respectively, which were not likely to have a meaningful impact on splicing. Therefore, all datasets processed prior to this upgrade were reanalyzed for indel variants. The TCGA ESCA dataset was reprocessed with a second set of RNAseq BAM files (see above response to point 3), which increased the fraction of flagged mutations for that tumor type. Finally, we processed an additional 7 tumor datasets from ICGC and included the validated mutations in our primary beacon database. The statistics of mutations, their distributions and support have been updated in the present version of the manuscript.

From our perspective, the proportion of variants validated is not “a surprisingly low fraction”. The results reported here are consistent with our previous published studies (Dorman et al., Sci. Rep. 4: 7063, 2014). Aside from NMD, as demonstrated below, some mutations that significantly alter splice site strength may not have been flagged by Veridical as a consequence of low levels of expression of the gene in the tumor (or controls) itself. Furthermore, Veridical cannot make an accurate assessment of the region of interest in control samples if these lack sufficient read abundance levels to determine the probability (p-value) of observing expression in the mutation-containing vs control samples. Also, our analysis did not take into account other impacts
of the variant on sequences that influence exon definition, such as binding to splicing regulatory factors or mRNA secondary structure. In our response to point 3, we described a discrepancy in BAM file sources, which could also lead to a lower fraction of confirmed variants. Finally, miscalled variants (despite the stringent quality control criteria applied to select variants) could contribute to the fraction of variants not supported by Veridical analysis. Such technical artifacts have been shown to be quite common in exome sequencing in areas of the genome characterized by low mappability (from Shi et al., Cell Rep. 2018 Nov 6;25(6):1446-1457, 2018): “Examination of the genomic locations of mutations revealed that 41.1% of the artifactual somatic mutations occurred in regions of low mappability compared with only 6.4% for the validated somatic heterogeneous mutations.”

As indicated in our response to point 3, the previous version of this paper only evaluated variants for their impact on constitutional mRNA splice sites and cryptic sites, and excluded impacts of mutations at splicing regulatory factor binding sites (SRFs). The scope and time required to assess SRFs precluded the reanalysis of all datasets for such changes. However, to address the issue raised by the reviewer, we evaluated the degree to which ignoring SRFs would affect the overall discovery of splicing-related variants. The updated version of the Shannon Pipeline (SP) with this capability was used to examine 1050 mRNA splicing variants that have been demonstrated to affect exon recognition (Cheung et al., Mol Cell. 2019 Jan 3;73(1):183-194.e8). These splicing variants were experimentally validated using a high throughput, multiplexed splicing minigene reporter assay in that study. SP reported a change in splicing and/or SRF binding strength for 1017 of these 1050 mutations (96.9%; where change in SRF strength was ≥ 3 bits). After accounting for SRF location (e.g. exonic TIA1 sites were eliminated, since these have not been proven to have splicing effects; see Table 1 of Caminsky et al., F1000Res.;3:282, 2014, for a full description of each SRF), the number of flagged variants was reduced to 940 (89.5%). Based on changes in constitutive splice site strength alone, 447 variants were flagged (435 weaken natural sites, 14 strengthen cryptic sites to a level exceeding the nearest natural site). Therefore, 46.3% of the constitutive mutations at natural or cryptic splice sites were also flagged by SP. This suggests that the lower predictive accuracy of SP in our original submission was, in part, due to the limitations in its ability to detect pathogenic mutations in SRF binding sites.

We addressed the reviewer’s suggestion to compare expression of the same gene in tumours with Veridical-validated mutations with other tumors with SP-predicted mutations in the same gene that were not experimentally validated. To perform the analysis, we obtained pre-processed mRNA expression data from the same RNAseq sources of TCGA patients from cBioPortal (www.cbioportal.com; provisional datasets were used, which contained largest number of patients for each tumor type). We extracted these gene expression values with a software program we wrote that determined transcripts per million (TPM) for each gene containing a SP-flagged variant. Expression values for gene present multiple times (due to the presence of multiple splice isoforms) were averaged for the particular tissue from which they were derived.

We separated mRNA expression values for each gene in TCGA patients into the Veridical-flagged vs. non-validated SP-predicted mutation categories, and performed a Student’s t-test on the two groups. The expression values of 58.2% of genes were statistically distinct with 90% confidence; >2 patients per category per gene). With at least 10 patients per category, the number of statistically different genes increased to 69.3%. Among these genes, patients with Veridical-flagged variants had higher overall gene expression in 99.7% of cases. These inherent differences in expression suggest that the failure to validate predicted mutations may be related to little or no expression of these genes in tumour and/or control samples, rather than to accuracy of
IT prediction methods. Non-sense mediated decay could be responsible for the decreased expression of these mutated genes in the tumour genomes that carry them, or the failure to validate could be related to low levels of expression of these genes in the particular tissues from which the tumours were derived. This analysis is now described in the revised manuscript (‘Dataset validation and discussion,’ para. 8).

Note: The gene expression data from cBioPortal had some limitations: 4196 genes containing variants flagged by SP are not present in the mRNA expression datasets, though the vast majority occurred in non-coding RNAs (i.e. 145 microRNAs, 194 LINC RNAs) or other uncharacterized RNAs (e.g. 324 ‘LOC’ RNAs). Furthermore, certain TCGA patients that we analyzed were not available in cBioPortal among the available expression datasets (2 TCGA-BRCA, 18 TCGA-COAD, 19 TCGA-GBM, 1 TCGA-HNSC, 1 TCGA-LUAD, 119 TCGA-OV, 4 TCGA-READ, 4 TCGA-STAD, 4 TCGA-THCA, and 7 TCGA-UCEC patients). Nevertheless, sufficient data were obtained for the analysis that we carried out.

Furthermore, this analysis has other caveats, especially regarding the accuracy of RNAseq quantification between samples, even upon normalization of the data. The vast majority of TCGA tumor samples do not have a matched normal counterpart, and many TCGA tumor datasets (e.g. TCGA-LAML) do not provide any normal control RNAseq data at all. While we could perform an analysis in which the tumor is compared to a set of normals for the same tissue, variation in expression between different individuals would obfuscate evidence of any apparent NMD caused by the mutation. A 50% reduction of expression (or less) may not be observable under these conditions.

5. In general, the authors seem to exclude that their prediction method could lead to false positives. Rather they justify the poor overlap with limitations of mRNA detection. If this is the case, this should be quantified and probably a comparison with other prediction methods could help.

Response: We have quantified RNA expression in tumors for mutations that were validated by Verical vs those which were not (see response to point 4). Regarding false positives: An extensive comparison of Information Theory to other bioinformatic programs which evaluate variants for splicing impact (MaxEntScan and Human Splice Finder) has been performed (Mucaki et al. 2013; Caminsky et al. 2014; see response to point 1). False positives are extremely rare because strength of binding sites (in bits) is directly related to their binding affinities; we have demonstrated that unused cryptic splice sites in the vicinity of natural splice sites are significantly weaker. Based on our experience and published analyses of a genome-wide site of binding sites (Rogan et al. 2003), such decoy splice sites are nearly always at least 4 bits (2^4 or 16 fold) weaker than sites that are actually recognized by spliceosomes.

The predictive accuracy of the IT methodology for detecting expression-validated mutations was determined to be 87.9% (762 of 867 variants from 122 different publications; changes to SRFs were included in this variant dataset; Caminsky et al. 2014). This value is similar to the predictions made to those of Cheung et al. (2019), where we predicted splice site and/or SRFs changes to 89.5% mutations experimentally validated to cause exon definition events.

The performance of IT-based methods for predicting splicing mutations has been well established over the past two and a half decades. Re-evaluation of its accuracy is not necessary, and this issue is, at best, only tangentially relevant, to the purpose of presenting the resource described in a
Data Note article.

6. Of the >351k mutations with an effect on splicing supported by RNA data, only 35 affect CGC genes. Is this only a subset of mutations affecting driver genes or is it the complete list? In the former case, I would suggest that the authors provide the full list as supplementary data. In the latter case, the authors should discuss the implication of such a low number. Considering that there are >700 CGC genes, does it mean that aberrant splicing is very rarely a driver event? Is the overwhelming majority of splicing variants passenger?

Response: There are 25 CGC genes indicated in Table 2, however these were never intended to be interpreted to be a complete list of CGC genes with Veridical-flagged mutations. The table has been renamed to indicate that these are a set of representative mutations. In the previous version of this paper, the number of variants (“n=25”) did not indicate the total number of CGC genes. This has been removed and replaced with the actual number of CGC splicing mutations that were validated:

“In Table 2, we highlight a subset of validated splicing mutations which were identified in known driver genes implicated in the COSMIC (Catalogue Of Somatic Mutations In Cancer) Cancer Gene Census catalog (CGC) 27. In total, 543 “Tier 1” CGC genes have at least one Veridical-flagged variant present in the ValidSpliceMut database.”

Competing Interests: Not applicable.

The increasing amount of sequencing data that is being generated in many biological systems has represented a real challenge to researchers in terms of trying to link individual changes to a particular biological process. The attempt, described in this work, to use IT approaches to evaluate the potential biological significance can significantly contribute to fill this gap. The laboratory of Peter Rogan has a long standing and internationally prominent role in addressing the possible consequences of sequence variants on the pre-mRNA splicing process especially with regards to its connection with human disease. The ValidSpliceMut developed in this work presents a user friendly interface that allows users to manually search for a variant (by gene name or genome coordinate range) and obtain information with regards to its possible effect on splicing. This will greatly help to better appreciate the functionality of Variants of Unknown Significance that are currently abundant genomic and transcriptomic Atlases.

Is the rationale for creating the dataset(s) clearly described?
Yes
Are the protocols appropriate and is the work technically sound?
Yes

Are sufficient details of methods and materials provided to allow replication by others?
Yes

Are the datasets clearly presented in a useable and accessible format?
Yes

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** I have more than twenty years experience in the investigation of pre-mRNA splicing processes and especially their potential connection with a variety of human diseases, both monogenic (Cystic Fibrosis, Pompe Disease, Neurofibromatosis) and polygenic (Amyotrophic Lateral Sclerosis, Frontotemporal Dementia). I am the author of more than 160 research papers in peer-reviewed publications and of several articles in scientific books on these subjects (orcid.org/0000-0002-1356-9074)

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

The benefits of publishing with F1000Research:

- Your article is published within days, with no editorial bias
- You can publish traditional articles, null/negative results, case reports, data notes and more
- The peer review process is transparent and collaborative
- Your article is indexed in PubMed after passing peer review
- Dedicated customer support at every stage

For pre-submission enquiries, contact research@f1000.com
