Abstract

**Background:** To obtain accurate measurements of cortisol (C) and testosterone (T) in Aceh cattle, commercial enzyme-linked immunosorbent assay (ELISA) kits need to be carefully validated. Moreover, repeated freeze-thaw cycles during the storage of the samples may affect the stability of the hormones in the serum. Here, we test the reliability of C and T concentration measurements in the serum of Aceh cattle, obtained using commercial C and T ELISA kits designed to measure human C and T concentrations. Further, we evaluate the effect of repeated freeze-thaw cycles on the stability of C and T concentrations in the serum.

**Methods:** Commercial C (Cat. no. EIA-1887) and T (Cat. no. EIA-1559) ELISA kits from DRG Instruments GmbH were validated through an analytical validation test (i.e., parallelism, accuracy, and precision) and a biological validation test (for C: effect of transportation on the C excretion; for T: the concentrations of T between bulls and cows). To test the effects of freeze-thaw cycles, cattle serum was subjected to the following treatments: (i) remained frozen at -20°C (control group); (ii) exposed to freeze-thaw cycles for two, four, six, and eight times (test groups).

**Results:** Parallelism, accuracy, and precision tests showed that both C and T ELISA kits adequately measured C and T in the serum of Aceh cattle. Concentrations of C post-transportation were significantly higher than pre-transportation (p<0.05). Concentrations of T in bulls were significantly higher than in cows (p<0.05). After four to eight freeze-thaw cycles, C concentrations were significantly lower compared to the control group (all p<0.05). In contrast, T concentrations remained stable (all p>0.05).

**Conclusions:** Commercial C (EIA-1887) and T (EIA-1559) ELISA kits are reliable assays for measuring serum C and T, respectively, in Aceh cattle.
reliable assays for measuring serum C and T, respectively, in Aceh cattle. Repeated freeze-thaw cycles significantly affected the stability of serum C, but did not for T.

Introduction
Cortisol (C) and testosterone (T) are steroid hormones. C is produced by the adrenal cortex, while T is produced by the Leydig cells in the testes. C has a key role in physiological stress responses. Accordingly, this hormone is commonly used as an indicator of stress. On the other hand, T plays an important role in male reproduction physiology. Thus, T levels can be used to assess male gonadal function.

Steroid hormones can be measured by an enzyme-linked immunosorbent assay (ELISA) technique using various samples (e.g., plasma or serum, urine, feces, saliva, and hair). This technique is now widely used, as it is simple, rapid, convenient, relatively inexpensive, requires a lower sample volume, and particularly, as it is free of radioisotope waste. Moreover, the availability of commercial ELISA kits makes it easy to apply this technique. However, because many commercial ELISA kits are usually designed for humans, using them for animals must be done with great caution and measurements are only trustworthy after the validation of the assay.

In order to reliably measure C and T concentrations in cattle using a human commercial ELISA kit, the ELISA kit needs to be validated analytically, physiologically or biologically. Analytical validation can be performed by examining the specificity (cross-reactions), sensitivity, precision, and parallelism (linearity) of the ELISA kit. In addition, it is crucial to perform the biological validation of the assay to examine the ability of the assay to differentiate the variation of the hormone concentration based on the physiological conditions of the animals. The biological validation of T measurements can be achieved by comparing the concentrations of T from individuals of different age (juvenile versus adult), or sex (male versus female) classes. For C measurements, the comparison of C concentrations of the same animal before and after some known stressful events (e.g., capture, translocation, transportation, and agonistic interactions) can be used as a biological validation procedure.

Another critical issue for hormone measurements is the repeated freezing and re-thawing of the samples (freeze-thaw cycles) during the storage prior to the analyses. Freezing the serum or plasma at -20°C or lower is an ideal storage method. However, power outages frequently occur, particularly in developing countries, and they can last for a few hours up to a day. Manuals of commercial ELISA kits always explicitly warn the users of several repeated freeze-thaw cycles. In this respect, the measurement of C and T can be used for informing husbandry management and breeding programs for this animal. In preparation for the first study to monitor reproduction and stress physiology of Aceh cattle, we test the reliability of commercial C and T ELISA kits designed for human serum/plasma to measure C and T concentrations in the serum of Aceh cattle. Moreover, we evaluate the stability of C and T concentrations in the serum of Aceh cattle after exposure to several repeated freeze-thaw cycles.

Methods
Ethical statement
The Institutional Committee of Animal Ethics of the Faculty of Veterinary Medicine, Universitas Syiah Kuala approved the use of all experimental animals in this study (Ref: 33/KEPH/VI/2019) (see Extended data). All efforts were made to ameliorate harm to the animals, such as: cattle were placed in the clamp cage to ensure quick, easy and safe collection of the blood sample causing minimal distress; blood samples were collected via the jugular vein without sedation, causing minimal distress. During the study, a member of the study team, accompanied by a veterinarian, observed their behavior for signs of excessive distress or sickness. None of the procedures performed in this study resulted in distress, sickness behavior or weight loss.

Study animals
Samples were collected from 12 adult Aceh cattle (aged two to five years old and weighing 150–300 kg) during two weeks in April 2019. This sample size was calculated based on Federer’s formula: \( t-1-(n-1) \geq 15 \), where \( t \) is the number of treatments and \( n \) is the number of animals. The sample size calculated using this formula is 16, but it was decided that a sample size of 12 animals would be satisfactory for statistical analysis. Six adult males (bulls) were sampled from a smallholder farmer at Darussalam, Aceh Besar, Aceh Province. These bulls were housed in stables, with each bull was separated by a wooden partition (individual housing system). Six adult female (cows) were sampled from a teaching farm (UPT hewan coba), Faculty of Veterinary Medicine, Universitas Syiah Kuala, Banda Aceh. These cows were housed together in stables (colony housing system). Cattle housing was equipped with feed and water troughs and food and water were consumed by the cattle ab libitum.

Collection and processing of blood samples
Blood samples (around 5 ml per animal) were collected inside on the farm by a veterinarian from the jugular vein using standard operating procedure without sedation. For the biological validation of C, blood samples were collected in the afternoon (16.00 to 18.00), while for the biological validation of T, blood samples were collected in the morning (06.00 to 08.00). Afterward, the blood was allowed to clot at room temperature for between 30 minutes and two hours. Then, the serum was separated from the red blood cells by centrifugation at 1200xg for 10 minutes at 4°C. After that, the supernatant...
T concentrations were measured for all serum samples together.

Validation of commercial C and T ELISA kits

To test the capability of the commercial C and T ELISA kits in quantifying concentrations of T and C in the serum of Aceh cattle, the commercial C (Cat. no. EIA-1887) and T (Cat. no. EIA-1559) ELISA kits produced by DRG Instruments GmbH, Germany, were evaluated using analytical and biological validations. The procedure for assay validation was conducted as described by Rangel-Negrin et al.\(^4\) and Gholib et al.\(^5\). Briefly, the analytical validation was comprised of parallelism (i.e. running serial dilution of Aceh cattle serum 1:2 to 1:16, assayed together with C and T standards, and comparing the slope of expected dose versus percent bound of diluted Aceh cattle serum with the slope of C and T standards), accuracy (i.e. adding known quantities of hormone to C and T standards and calculating the percentage of recovery), and precision (i.e., measuring some low-quality controls (QC L) and high-quality controls (QC H) in one microplate to calculate intra-assay coefficients of variation (CV) and some QC L and QC H in several microplates to calculate inter-assay CV. The sensitivity was reported as provided by the manufacturer.

For the biological validation of C, we examined the effects of transportation on the C excretion. We used five of the Aceh cattle described above (two bulls and three cows). Bulls and cows were transported using different road vehicles (open car) around Banda Aceh at 11.00 a.m for an hour (~40 km/hour). During transportation, cattle were secured using a rope around their neck and bulls and cows were transported using different vehicles. We predicted that C concentrations should be higher following transportation. We collected serum a day before transportation and four hours after transportation. Serum was collected as described above. For the biological validation of T, we compared the concentrations of T from six bulls and six cows and predicted that the T concentration should be higher in bulls.

Experiment design of freeze-thaw cycles

To evaluate the stability of C and T concentrations in serum exposed to repeated freeze-thaw cycles, we took seven serum samples (three bulls and four cows) collected from the previous experiment (biological validation of C and T) to be used for the freeze-thaw cycle experiment, in order to avoid several blood sample collections. Each serum sample was then divided into five aliquots and transferred into 1.5 ml micro-tubes (Eppendorf Safe-Lock tubes; total 35 aliquots; 0.2 ml per tube), closed tightly and sealed with parafilm. All aliquots were subsequently stored frozen at -20°C. Later, those aliquots were subjected to the following treatments: (i) aliquots remained frozen at -20°C until the time of hormone analysis as a control group (N=7); and (ii) aliquots were exposed to repeated freeze-thaw cycles for two, four, six, and eight cycles as test groups (N=7 for each group). The serum was thawed for six hours by placing the tube in a room without an air conditioner (mean of temperature 27.6±0.7°C). Afterward, the serum was refrozen for 24 hours prior to re-thawing. After all freeze-thaw cycles were completed, C and T concentrations were measured for all serum samples together.

C and T concentration measurements

The concentration of C was measured using a commercial C ELISA kit (Cat. no. EIA-1887, DRG Instruments GmbH, Germany). The assay utilizes a monoclonal anti-cortisol antibody and C labeled with horseradish peroxidase as an enzyme conjugate. The measurement of C was conducted following the instructions of the manufacturer (DRG diagnostics). In brief, 20 μl of each standard, control, and samples (serum) in duplicate were dispensed with new disposable tips into appropriate wells on a microplate coated with C monoclonal antibody. After that, each microplate well was filled with 200 μl enzyme conjugate, thoroughly mixed, and then incubated for 60 minutes at room temperature. After incubation, the solution in the wells was briskly shaken out and rinsed out with 350 μl diluted washing solution per well four times. Furthermore, 100 μl substrate solution (tetramethylbenzidine) was added to each well of the microplate, which was then re-incubated for 15–20 minutes at room temperature. After that, the enzymatic reaction was stopped by adding 100 μl of stop solution (0.5 M H₂SO₄) to each well. Finally, absorbance was determined by using an ELISA reader (xMark™ Microplate Absorbance Spectrophotometer, Bio-Rad Laboratories Inc.) at 450 nm. The C concentration was then calculated using the Microplate Manager\(^6\) 6 Software (Bio-Rad Laboratories Inc.).

The concentration of T was measured using a commercial T ELISA kit (Cat. no. EIA-1559, DRG Instruments GmbH, Germany). The assay utilizes a mouse monoclonal anti-testosterone antibody and T labeled with horseradish peroxidase as an enzyme conjugate. This assay has been previously validated successfully for measuring T concentrations in Kacang goats\(^4\). T measurements were conducted following the instructions of the manufacturer (DRG diagnostics) and as described by Gholib et al.\(^5\). In brief, 25 μl of each standard, control, and samples (serum) in duplicate were dispensed with new disposable tips into appropriate wells on a microplate coated with T monoclonal antibody. After that, each microplate well was filled with 200 μl enzyme conjugate, thoroughly mixed, and then incubated for 60 minutes at room temperature. Following this, the microplates were treated and absorbance was measured as described above for C.

Data analysis

Normality distribution of the data was tested using the Shapiro-Wilk test prior to statistical analysis. For the analytical validation, the parallelism between serial dilutions of two selected serum samples and standard curves was determined by a test of equality of two slopes\(^3\). For the biological validation, C data before and after transportation showed a normal distribution (p>0.05), whereas T data of bulls and cows did not (p<0.05). A paired t-test was used for C, whereas for T, a Mann-Whitney U test was used. For the freeze-thaw cycles experiments, the proportion of change in C and T concentrations relative to the control was calculated as (aₙ – xₑ / xₜ) x 100, where aₙ is the nth sample value in each freeze-thaw cycles series (two, four, six, eight times) and xₑ is the value at time zero (control) of the nth sample.\(^7\)\(^14\) The C data were normally distributed (p>0.05), whereas the T data was not (p<0.05). Therefore, for C, a one-way repeated measures ANOVA followed
by post hoc analysis using the Bonferroni test was conducted, whereas a Friedman repeated-measures ANOVA on ranks was set up to analyze T concentrations. We used SigmaPlot 11.0 to create graphs and IBM SPSS 20 to carry out the statistical analysis. All statistical tests were two-tailed and the significance level was set at 0.05.

Results

The validity of commercial ELISA kits for measuring C and T in the serum of cattle

The serial dilution of the selected serum showed displacement curves that were parallel to C and T standard curves (Figure 1, Table 1). The parallelism, dose-response, accuracy, and

**Figure 2.** Results of the biological validation of the commercial enzyme-linked immunosorbent assay (ELISA) kits. a) Concentrations of cortisol (C) before (pre-trans) and after (post-trans) transportation measured using a commercial C ELISA kit (DRG, Cat. No. EIA-1887). b) Concentrations of testosterone (T) in bulls and cows measured using a commercial T ELISA kit (DRG, Cat. No. EIA-1559). Different superscripts above line symbols and histogram indicate a significant difference between groups (p < 0.05).

**C and T stabilities after exposure to repeated freeze-thaw cycles**

Repeated freeze-thaw cycles in serum significantly affected the stability of C concentrations (F[4,30] = 11.681, p<0.001, N=7; Table 2). *Post hoc* analysis showed that after four to eight freeze-thaw cycles, the C concentrations were significantly lower than those of the control group (all p < 0.05; Table 2, Figure 3A). In contrast to the C concentrations, the T concentrations remained stable after exposure to two to eight freeze-thaw cycles (χ²[4] = 7.626, p = 0.106, N = 7; Table 2, Figure 3B). The mean percentage of change in C and T concentrations ranged between 13.43 to 33.94% and 3.55 to 8.33%, respectively, relative to the control group (Figure 3). Raw values of C and T concentrations are given in Dataset 3 (see Underlying data).
Discussion

In the current study, we demonstrate that C and T concentrations in the serum of Aceh cattle can be accurately measured using the commercial C and T ELISA kits designed for human C and T measurements. The results of the parallelism test show that the slope of the diluted sample curves was parallel to the standard curves of commercial C and T ELISA kits. In addition, concentrations of C and T decreased significantly following the dilution levels. Furthermore, these assays also show high accuracy (~100%) and precision (CV < 10% and < 15% for intra- and inter-assay, respectively). Therefore, both the commercial C ELISA kit and the commercial T ELISA kit tested can be used to measure C and T concentrations, respectively, reliably in the serum of Aceh cattle.

A significant increase in C excretion after transportation was detected by the commercial C ELISA kit tested (Figure 2A). This result was to be predicted because C is the main modulator of physiological stress and it will increase in response to a stressor. The commercial T ELISA kit also appeared reliable in its ability to discriminate T concentrations between bulls and cows. T concentrations in bulls were more than five times higher compared to cows. This result was to be expected because T is the major androgen produced by the Leydig cells of the testes, whereas only small amounts are secreted in the adrenal cortex and ovaries of females.

Our results indicated that the biological validation of commercial C and T ELISA kits can be performed using C measurements in relation to a stressful event and T measurements of different sexes. It is crucial to conduct such as validation to ensure the biological meaningfulness of the analyses. EIA-1887 and EIA-1559 are commercial ELISA kits developed for measuring hormone concentrations, particularly in human serum/plasma. These assays use an antibody highly specific to either C or T. The antigen (C or T) in the serum of Aceh cattle can bind correctly with the antibody (anti-cortisol and anti-testosterone) in these ELISA kits because the side-chains of the carbon compounds of C (C-21) and T (C-19) have similar structures in vertebrates. The validation of commercial ELISA kits for measuring hormones in animals has been successfully conducted in several animals, such as progesterone in cattle, estradiol and inhibin A in buffalo, C in horses, and T in Kacang goats.

In addition to the validation of ELISA kits, we tested the effects of repeated freeze-thaw cycles on the stability of C and T concentrations in serum. Concentrations of C decreased significantly after the exposure to four, six, and eight freeze-thaw cycles (p<0.05), while T concentrations did not (p>0.05). Concentrations of C declined up to 33.94% after eight freeze-thaw cycles, whereas the percentage changes in T concentrations were less than 10% in all test groups. These findings show that T is more resilient to freeze-thaw cycles compared to C. The reason why C and T concentrations decreased after exposure to repeated freeze-thaw cycles is not entirely clear. It is possible, however, that the serum left at high temperatures (27.6±0.7°C) during the six hours of the thawing process might facilitate the increased

Figure 3. Percentages of hormone concentrations in the serum exposed to repeated freeze-thaw cycles compared to control. (a) Cortisol (C). (b) Testosterone (T). Values represent mean±SD relative to control (100%). Different superscripts above histogram indicate a significant difference between groups (p < 0.05).
degradation of C and T\textsuperscript{15}. Consequently, less antigen in the serum binds with the antibody of the assay\textsuperscript{37}. Thus, C and T concentrations in all test groups were lower than the control group.

From a practical point of view, our results suggest that commercial C (EIA-1887) and T (EIA-1559) ELISA kits can accurately measure C and T concentrations, respectively, in the serum of animals such as Aceh cattle. It can advantageous to use these commercial assays over assays specifically designed for animals because of their relatively low price. On the other hand, repeated freeze-thaw cycles must be considered, especially for the C measurement. Therefore, conditions that may potentially cause repeated freeze-thaw cycles of samples designated for hormone analysis (e.g. frequent power outages) should be avoided. Some efforts can be performed to prevent the possibility of repeated freeze-thaw cycles, such as installing a backup generator in each laboratory to supply electricity when there are power outages, filling each freezer with a blanket of ice packs to maintain the temperature inside the freezer during the power outage, averting the use of an aliquot of serum/plasma for several analyses at different times, and dividing serum into several aliquots when several analyses should be performed from the same sample\textsuperscript{15}.

This study has some limitations: first, the small sample size used; and second, the information regarding the substantive reason for decreasing C and T concentrations after repeated freeze-thaw cycles is still unclear. To elucidate this reason, the biochemistry of the serum after exposure to freeze-thaw-cycles needs to be investigated in future studies. Moreover, it was unclear whether these assays are also reliable for other animals, so they would need a validation test for each animal. Apart from the fact that there are limitations, the results are important to support further studies in Aceh cattle, particularly for maintaining and growing the Aceh cattle population to ensure food security in the Aceh region and Indonesia as a whole.

In conclusion, our study shows that commercial C (EIA-1887) and T (EIA-1559) ELISA kits are reliable assays for measuring serum C and T, respectively, in Aceh cattle. We also demonstrate that more than two repeated freeze-thaw cycles significantly affected the stability of serum C concentrations, but up to eight repeated freeze-thaw cycles did not significantly affect the stability of serum T concentrations.

The authors validated an EIA for testosterone and cortisol detection in serum of Aceh cattle. They also performed the biological validation of both hormones in serum. And finally, they evaluated the effect of freeze-thaw cycles on the stability of these hormones in serum.

Although the technique they present is not new, the validation the authors perform are imperative for the proper hormone interpretation in every matrix, and thus this should be done for each species, matrix and assay of interest. The study has a robust experimental design despite using a low number of samples in some experiments. Results they present are very useful and may provide guidance for future studies to perform appropriate validations of their methods.

My major concern is why the authors discuss that T is affected by the freeze-thaw cycles if results do not indicate the same. Additionally, I would suggest dividing the aims in three: analytical validation, biological validation and freeze-thaw cycles, as they may provide three different results and conclusions. I have also added some minor comments which can be found in the pdf document that I hope they will be useful for the authors.

Is the work clearly and accurately presented and does it cite the current literature?
Yes

Is the study design appropriate and is the work technically sound?
Partly

Are sufficient details of methods and analysis provided to allow replication by others?
Yes

If applicable, is the statistical analysis and its interpretation appropriate?
Partly

Are all the source data underlying the results available to ensure full reproducibility?
Yes

Are the conclusions drawn adequately supported by the results?
Partly

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** Endocrinology and animal stress

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.
Yes

Are all the source data underlying the results available to ensure full reproducibility?
Yes

Are the conclusions drawn adequately supported by the results?
Yes

Competing Interests: No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

The benefits of publishing with F1000Research:

- Your article is published within days, with no editorial bias
- You can publish traditional articles, null/negative results, case reports, data notes and more
- The peer review process is transparent and collaborative
- Your article is indexed in PubMed after passing peer review
- Dedicated customer support at every stage
