Abstract
The Mekong Delta paddies are known as hotspots of methane emission, but these emissions are not well studied. We analyzed methane emission patterns based on monitoring data from typical triple rice cropping paddies collected over 5 years. We found that the total emissions in a crop season doubled in the second crop, tripled in the third crop, and reset after the annual natural flood of the Mekong River. The emission peaks occurred around 0 to 3 weeks after starting irrigation, then gradually decreased. This suggests that methane was generated by the soil organic matter, because the small rice plants provide little carbon for methanogenesis. In general, the main source of emitted methane is rice-derived carbon by current-season photosynthates and the emission peaks at the rice heading stage. However, the contribution of the rice-derived carbon is negligible in the hotspot paddies while total emission is high. The increase in emission levels from the first to the third crop can be explained by the accumulation of rice residue from the preceding crops, especially rice straw incorporated into the soil. The reset of emission levels after annual flood means that the rice straw is decomposed without methanogenesis in water with dissolved oxygen. Thus, the annual emission pattern shows that decomposing rice straw in paddy surface-water is an effective method to reduce methane emissions.

Introduction

Vietnam is the world’s fifth largest rice producer (FAO 2018). The Mekong Delta produces the half (23.8 million tons) (General Statistics Office of Vietnam 2016). The climate of tropical monsoon (Am) enables high productivity by triple rice cropping (cropping three times a year). Rice paddies are a methane emission source, and the Mekong Delta is a hotspot (Arai et al., 2018; Werner et al., 2016). The high emissions are caused by the rice straw incorporation (Oda & Chiem, 2019). However, the methane emission of triple rice cropping has not been well studied (Vo et al., 2018).

The Mekong’s natural flood of two months (starting from around late September to late October) limits the rice cultivation period. The 1st crop (winter-spring) begins after the natural flood, then after harvesting the rice straw is incorporated into the soil. The 2nd (spring-summer) and the 3rd crop (summer-autumn) follows without interval. Just after the 3rd crop, the natural flood starts so the straw is left on the paddies and decomposes under the floodwater. Then, the 1st crop begins again without incorporation of the straw in the soil (field leveling only), because they are sufficiently decomposed by that time.

Can Tho University (CTU) and the Japan International Research Center for Agricultural Sciences (JIRCAS) conducted joint research and monitored methane emissions in typical triple rice cropping paddies for 5 years (for a total of 15 crops). This paper is a specific analysis of a part of the data set from this project. The results show that the strategy of decomposing rice straw on the surface water effectively reduces methane emission from the paddies.

Methods

Site description

The observation was conducted on a farmer’s paddies (three fields) managed by the above typical triple-cropping in Thuan Hung village (10°22' N, 105°58' E), Thot Not district, Can Tho city, Vietnam from 2011 to 2016. The soil is alluvium soil (Aquic Tropaquepts). Normally, from May to October is the rainy season. The farmer managed the water with continuous flooding using a dike system. The rice (Oryza sativa) variety Jasmine was used for the 1st crop, and OMS01 was used for the 2nd and 3rd crop every year. The average number of growth days per crop were 103, 89, and 92, for the 1st, 2nd, and 3rd crops, respectively. The average intervals between the 1st and the 2nd crop and the 2nd and the 3rd crop were 5.6 and 6.6 days, respectively. The average rice straw dry weight per crop were 9.0, 9.3, and 7.4 (Mg ha⁻¹), for the 1st, 2nd, and 3rd crops, respectively, and the whole amount were returned. This study was conducted with the approval of the farmer.

Methane measurement

We used the closed chamber method established by NARO and IRRI (http://globalresearchalliance.org/research/paddy-rice/), and the measurements were taken at 8 a.m. (ca. 90% of the average daily emissions). In periods of natural flood, chambers with attached Styrofoam floats were used. Measurements were taken once a week throughout the rice growing stage, but every 3 days for 2 weeks after seeding, heading stage, and around draining (Oda & Chiem, 2019).

Statistical analysis

The cumulative CH4 emissions were calculated by linear interpolation. Descriptive statistics were calculated using Microsoft Excel 2016.

Results

Emission level

According to the IPCC guidelines, standard methane emissions over 100 days of continuously flooding rice cropping are 130 kg ha⁻¹ crop⁻¹. Wassmann et al. (1996) reported very high emissions (160–240 kg ha⁻¹ crop⁻¹) from double cropping rice paddies in the Philippines after organic matter incorporation. However, we observed larger emissions (710, 1290, and 1789 kg ha⁻¹ crop⁻¹), for the 1st, 2nd, and 3rd crops in average, respectively. Vo et al. (2018) measured the same level of emission in the Mekong delta (ca. 900 kg CH4 ha⁻¹ crop⁻¹). The emission level doubled in the 2nd crop, and tripled in the 3rd crop, then reset after the natural flood (Figure 1). Furthermore, the total emissions during the flood period and the 1st crop was lower than that of the 3rd crop (Figure 1). The total emission of the flood period should be higher than that of the 3rd crop; because, the accumulation of organic matter is larger. In addition, although the absence of rice-derived carbon, the absence of rice plants doubles the methane emission from the field because of the lack of methanogenesis inhibition by rice plants (Oda & Chiem, 2019). Note, we confirmed that no rice straw (the source of methanogenesis) was lost to the floodwater. Raw results are available as Underlying data (Oda, 2019a).

Emission pattern

Oda & Chiem (2019) indicated three types of methane emission patterns during the rice growth period. Generally, the emissions peak at the heading stage due to the methanogenesis substrate provided by the present rice. Another pattern can occur with an additional peak at the early stage of rice growth if organic matter was incorporated beforehand. The third is the pattern in the triple rice cropping. The emission peaks at the early stage of rice growth, then gradually decreases; the peak at the heading stage is undetectable because of the high emission levels. This means the contribution of the rice-derived carbon is small. The pattern of methane emission was
the same as the study of Oda & Chiem (2019). The emissions began with irrigation, reached peaks from 0 to 3 weeks after the start of irrigation (see Extended data, Supplemental figure; Oda, 2019b), and gradually decreased, and the peak at the heading stage was undetected. Furthermore, the emissions during the natural flood appeared to be a continuation of the emissions of the 3rd crop (Figure 2).

**Discussion**

**Emission pattern**

The total emissions in a crop season doubled in the second crop, tripled in the third crop, and reset after the natural flood. This can be explained by the accumulation of rice residue from the preceding crops, especially by the rice straw incorporated into the soil, because the contribution of the present rice-derived carbon is small (Oda & Chiem, 2019). Remember that just after the 3rd crop, the natural flood starts so the straw is left on the paddies. No rice straw is incorporated before the flood period. That is the difference in the conditions of Oda & Chiem (2019).

The reset of emission levels after the annual flood means that the rice straw is decomposed without methanogenesis in water because the water includes dissolved oxygen. Convection of surface water transports new water to rice straws and new oxygen replenishes from the atmosphere when reducing the concentration of dissolved oxygen. Thus, the redox potential of water hardly achieves the level of methane generation. The fact that the emissions under natural flood appeared to be a continuation of the emissions of the 3rd crop suggests that the rice straw on the paddy surface contribute to little methane emission. A portion of emission in the first crop will be caused by incorporation of the remaining rice straw related to the leveling of the field.

**Method for methane reduction**

Our results indicate that the main cause of the increase in methane emissions was the incorporation of rice straw into the soil. In contrast, decomposing rice straw in paddy surface-water generated less methane. Thus, decomposing rice straw in paddy surface-water is an effective method to reduce methane emissions.

**Conclusion**

We analyzed the methane emission patterns of triple rice cropping paddies in the Mekong Delta. Methane emissions increased with rice straw incorporation into the soil. The natural flood resulted in decomposition occurring in the water, leading to

---

**Figure 1. Total CH₄ emissions.** Five-year average of CH₄ emissions of triple-cropped rice paddies in the Mekong Delta (2011–2016). Bars represent 95% CI (n = 5).

**Figure 2. Actual CH₄ emissions.** CH₄ emissions of triple crop rice paddies in the Mekong Delta (2011–2016). Data are the mean of three replications. Irrigation started 6 days after seeding and drained about 10 days before harvesting. The average days of interval between the harvesting and seeding was 6.1 days. The heading stage of the rice is about a month before drainage.
less methane emission. Therefore, the annual emission pattern suggests that decomposing rice straw in paddy surface-water is an effective method to reduce methane emissions. The development of practical technology to attain this reduction is a subject for a future study.

I read the revised manuscript (ver. 5) and the Author Response (dated on 23 Mar 2020) to my comments on its ver. 4 (12 Mar 2020) that was reported me on 26 Jun 2020. Although some revisions have made in the manuscript, the latest version of the manuscript (ver. 5) still has a number of problems and misunderstandings in presentation and interpretation of the experiment and its results. I do not recognize the revisions in response to most of my previous comments to ver. 2 and 4. As a result, in conclusion, I have to report that the response is still unsatisfactory to accept.

Competing Interests: No competing interests were disclosed.

Reviewer Expertise: biogeochemistry, soil science

I confirm that I have read this submission and believe that I have an appropriate level of expertise to state that I do not consider it to be of an acceptable scientific standard, for reasons outlined above.

Author Response 14 Jul 2020

Masato Oda, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

We hope the misunderstandings should be clarified in the response so that we could know the misunderstandings. You didn't give us any response so we understood that you accepted our response. You and we should reduce the effort of the Editorial Team.
In summary, the manuscript is still lacking in scientific sound and requires extensive revision. The contradictions between this finding and the previous studies have not yet been logically justified. Oda and Chiem (2019) mentioned the methanogenesis inhibited by rice plants, but this study shows higher methane during the cropping cycles than those in the non-cropping phase. The authors said that "No rice straw is incorporated before the flood period. That is the difference in the conclusion of Oda and Chiem (2019)." It is not clear to me what "incorporated" means and how it results in the different outcomes between these two studies. Is it sound inconsistency with the statement that "We confirmed that no rice straw (the source of methanogenesis) was lost to the floodwater."

The authors persuaded that the no-plant flood mentioned in Oda and Chiem (2019) had no rice straw, but in this study, there was straw left in the field during the natural flood. The authors also conclude that soil organic alone under flooding promotes methane emission, but soil organic with rice straw incorporated was not. The authors said that the reason is due to sufficient DO. This conclusion was puzzling. How to prove that the flood in the previous study has insufficient DO, but there was adequate for this study? The authors, therefore, should discuss more the pathways of C losses (CH₄, CO₂, SOC, Dissolve forms, bio uptake, etc.) from the paddy field during the natural flood.

The authors point out that decomposing rice straw in non-cropping flooding water generates less methane under sufficient DO so that they recommend the audiences to experiment as a way to minimize methane emission. This recommendation might not be useful and need to open for multidisciplinary discussions. First, the cropping environment factor should be discussed in response to the limitation and possible adoption of this CH₄ mitigation practices in other areas. Second, socioeconomics should be firmly pointed out since minimizing cropping cycles may not be socially acceptable. Third, environmental sustainability by CH₄ mitigation may not correct since the conversion of CH₄ to other carbon forms could also result in additional ecological problems.

Author Response 14 Jul 2020

Masato Oda, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

"Incorporation" means rice straw is incorporated into the paddy soil by tillage. We ask you to read the references.

**Competing Interests:** No competing interests were disclosed.

Author Response 26 Aug 2020

Masato Oda, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

1) It is not clear to me what "incorporated" means and how it results in the different outcomes between these two studies.

We've noticed that a sentence is unclear to indicate the work of Oda & Chiem *2019). We revised the manuscript as follows.

**Discussion- Emission pattern**

"The total emissions in a crop season doubled in the second crop, tripled in the third crop, and reset after the natural flood. This can be explained by the accumulation of rice residue from the preceding crops, especially by the rice straw incorporated into the soil. Because the contribution of the present rice-derived carbon is small ( Oda & Chiem, 2019). Incorporation of organic matter just before rice cultivation largely increases the methane emission in the paddy field ( Wassmann et al., 1996). However, that just after the 3rd crop, the natural flood starts so the straw is left on the paddies. No rice straw is incorporated into soil before the flood period and that resulted the reduction of CH4 emission."

2) How to prove that the flood in the previous study has insufficient DO, but there was adequate for this study?

The difference of DO is clear because the location of rice straws is different. We emphasized this by adding the reference of Wassmann et al. in the above paragraph.

3) This recommendation might not be useful and need to open for multidisciplinary discussions.

We revised the manuscript as follows.

"Our results indicate that the main cause of the increase in methane emissions was the incorporation of rice straw into the soil. In contrast, decomposing rice straw in paddy surface-water generated less methane. Thus, decomposing rice straw in paddy surface-water is an effective method to reduce methane emissions in this area. However, environmental sustainability should be considered the conversion of CH4 to other
carbon forms could also result in additional ecological problems. In addition, socioeconomics should be considered since minimizing cropping cycles may not be socially acceptable."

The conclusion also added the following sentence.
"However, the effects of CH4 conversion to other carbon forms and of socioeconomics should be clarified."

**Competing Interests:** No competing interests were disclosed.

---

**Author Response 26 Jan 2021**

**Masato Oda,** Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

First, the purpose of this study is not to propose a technology. Therefore, in the revised manuscript, we limited our conclusions to the results of the analysis.

Second, you have pointed out the contradiction with existing studies, but the two are not contradictory.

The point is not whether there is rice straw in the rice paddies, but whether the straw is incorporating into the soil. In the revised manuscript, I clearly stated: "incorporating into the soil" to avoid misunderstanding.

The data show that the methane production is obviously different depending on whether the rice straw is in the soil or in the water. Also, if the rice straw is not continuously incorporated into the soil, the amount of methane produced is smaller.

Methane is produced in a reduced state. In other words, the reduction of methane production in the presence of large amounts of rice straw is evidence of the presence of dissolved oxygen. The revised manuscript explained in detail the continuous supply of dissolved oxygen in the water.

**Competing Interests:** No competing interests were disclosed.

Consistently, the authors have not well communicated in their writing and poorly reviewing the previous studies resulting in devaluing the work despite interesting methodology. For example, the authors cited their own articles, and readers cannot clearly distinguish ones from the previous studies and one of this study. Though, there is some inconsistency between the previous study of Oda and Chiem (2019) — “the absence of rice plants doubles the methane emission from the field because of the lack of methanogenesis inhibition by rice plants” — and the Figure 1 of this study. The authors are not attempting to discuss this inconsistency but try to discuss their new findings without citing any supporting evidence from other previous works.

**Competing Interests:** No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to state that I do not consider it to be of an acceptable scientific standard, for reasons outlined above.

---

**Author Response 22 Apr 2020**

Masato Oda, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

Thank you for reviewing and we are sorry to late to respond.

1) For example, the authors cited their own articles, and readers cannot clearly distinguish ones from the previous studies and one of this study.

Oda & Chiem (2019) is a field experiment conducted in the year 2018; instead, this work is "a specific analysis of a part of the data set; Introduction L. 15" of an old project (2011-2016). We are sorry that the relation is a little complicated; however, that is a fact. What we call "data analysis" can do at any time.

We welcome if you give us a piece of advice for the way to dissolve this problem.

2) There is some inconsistency between the previous study of Oda and Chiem (2019) — “the absence of rice plants doubles the methane emission from the field because of the lack of methanogenesis inhibition by rice plants” — and the Figure 1 of this study. The authors are not attempting to discuss this inconsistency but try to discuss their new findings without citing any supporting evidence from other previous works.

The sentence is in the result section and the inconsistency is discussed in the discussion sections as follows.

"This can be explained by the accumulation of rice residue from the preceding crops, especially by the rice straw incorporated into the soil, because the contribution of the present rice-derived carbon is small; Discussion L. 2"
Remember that "Just after the 3rd crop, the natural flood starts so the straw is left on the paddies; Introduction L. 10". No rice straw is incorporated before the flood period. No rice straw is incorporated before the flood period. That is the difference in the conditions of Oda & Chiem 2019.

We are waiting that your response.

**Competing Interests:** No competing interests were disclosed.

Reviewer Report 17 March 2020

https://doi.org/10.5256/f1000research.25143.r61258

© 2020 Yagi K. This is an open access peer review report distributed under the terms of the Creative Commons Attribution License, which permits unrestricted use, distribution, and reproduction in any medium, provided the original work is properly cited.

Kazuyuki Yagi
The Joint Graduate School of Energy and Environment (JGSEE), Center of Excellence on Energy Technology and Environment, King Mongkut's University of Technology Thonburi, Bangkok, Thailand

I read the revised manuscript (ver. 4) and the Author Response (dated on 21 Feb 2020) to my comments on its ver. 2 (12 Nov 2019) that was reported on 19 Feb 2020. As a result, I found that the response was quite unsatisfactory to accept.

The authors responded to many of my comments that they think the matter of writing style is not constructive. However, I do not agree with that because those comments are not the matter of writing style but that of fundamental requirements for a scientific paper. I cannot understand their statement that ‘because that is largely affected by the background of the main journal we have read’.

Also, the term 'natural flood' or 'annual flood' is still unclear. It is written that 'natural flood of two months (starting from around late September to late October) limits the rice cultivation period. The 1st crop (winter-spring) begins after the natural flood, ... (Introduction, 2nd paragraph lines 1–4). Then, when was the period ‘Flood’ in Figure 1? It is difficult to understand the periods written in the 'Emission level' section of Results: 'after the natural flood (line 11)', 'during the flood period and the 1st crop (lines 12–13)', and ‘the flood period (line 14)’.

In addition, the response to other minor comments are not satisfactory as listed below:

- Management of rice straw: Authors added the average rice straw dry weight, but it is still unclear how much of the straw was returned to the soil.
Statistical analysis: Authors added 95% CI and the numbers of replication, but not analyzed the significance of difference between seasons.

After Vo et al., 2018 has published, it cannot say 'these emissions are not well studied'. Also, the knowledge in the IPCC Guidelines should be cited and included.

The details of the soil properties should be provided if they have not been published in another paper.

The reason why the result was not consistent to the ‘previous’ report (Results, Emission level, Lines 13–15) is still unclear. The ‘previous’ report (Oda & Chiem, 2019) reported that rice suppressed overall methane emissions.

In conclusion, because of the result of above-mentioned assessment, I have no other choice to recommend 'reject' for this paper, despite that it includes original and remarkable findings that are valuable to the scientific communities.

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** biogeochemistry, soil science

I confirm that I have read this submission and believe that I have an appropriate level of expertise to state that I do not consider it to be of an acceptable scientific standard, for reasons outlined above.

---

**Author Response 23 Mar 2020**

**Masato Oda**, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

*The authors responded to many of my comments that they think the matter of writing style is not constructive.*

That's a misunderstanding. That is because we think most of your comments are not the matter of writing style but that of fundamental requirements for a scientific paper.

*When was the period ‘Flood’ in Figure 1?*

You can see the period in Figure 2.

*How much of the straw was returned?*

We returned all; therefore, we don't mention how much.

*Significance test*

That means significant at 5% level when the 95%CI do not overlap.

*Soil properties*

We can show a paper which conducted the same place. The paper shows that the soil is the silty-clay Fluvisol soils (clay 52%, silt 48%, sand 0.3%; FAO Soil Classification; Arai et al. 2015).
*The reason why the result was not consistent to the ‘previous’ report*

That is explained in the discussion section as follows. "The reset of emission levels after the annual flood means that the rice straw is decomposed without methanogenesis in water". This high emission resulted from rice straw incorporation.

**Competing Interests:** No competing interests were disclosed.

**Arika Bridhikitti**

Environmental Engineering and Disaster Management Program, Mahidol University Kanchanaburi Campus, Kanchanaburi, Thailand

This improvement has been more scientific sounds. The authors discuss based on the experimental results. The manuscript; however, has major concerns on the unclear conclusion, miscommunication, and writing problems.

**Methods:**
- Rice variety should be firstly introduced in scientific names.

**Results:**
- Unbalance parenthesis when introducing the methane emissions from 1st, 2nd, and 3rd cropping periods.
- The sentence on “The total emission should be higher than that of the 3rd crop: because the absence of rice plants doubles the methane emission from the field (Oda and Chiem, 2019)” is not understandable. What is the total emission? Why does the absence of rice plants cause double emission?
- The sentence on “In the present study, the pattern was the same as the previous study (Oda and Chiem, 2019)” is also hard to understand. What is the present study? Oda and Chiem (2019) or this study? If the author means this study, it was also not the same as the previous study since no emission peaked at the heading stage.
- Figure 2 should provide additional information on the heading stage, irrigation period, and period of the full canopy development.
**Discussion:**

- the sentence on “the rice straw is decomposed without methanogenesis in the water because the water includes dissolved oxygen” is doubtful. The author should discuss more how CH$_4$ forms without methanogenesis and how to be confident that the DO in the water did not deplete for the entire 2-month flooding.

**Competing Interests:** No competing interests were disclosed.

**Reviewer Expertise:** Environmental Engineer

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

---

**Author Response 09 Mar 2020**

**Masato Oda,** Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

We deeply thank you for giving valuable suggestions.

**Rice variety should be firstly introduced in scientific names.**

We added.

**Unbalance parenthesis.**

We corrected.

The sentence on “The total emission should be higher than that of the 3rd crop: because the absence of rice plants doubles the methane emission from the field (Oda and Chiem, 2019)” is not understandable. What is the total emission? Why does the absence of rice plants cause double emission?

We added the value of the total emission and clarified the sentence and added the reason.

The sentence on “In the present study, the pattern was the same as the previous study (Oda and Chiem, 2019)” is also hard to understand. What is the present study? Oda and Chiem (2019) or this study? If the author means this study, it was also not the same as the previous study since no emission peaked at the heading stage.

We clarified the sentence.

**Figure 2 should provide additional information on the heading stage, irrigation period, and period of the full canopy development.**

We added the information for the heading stage and the irrigation period. Unfortunately, we don't have data on the period of full canopy development.

**Discussion:**

the sentence on “the rice straw is decomposed without methanogenesis in the water because the water includes dissolved oxygen” is doubtful. The author should discuss more how CH$_4$ forms without methanogenesis and how to be confident that the DO in the water did not deplete for the entire 2-month flooding.
1) We added the explanation for CH4 forms without methanogenesis.
2) We added a possible explanation for the DO in the water did not deplete.

**Competing Interests:** No competing interests were disclosed.
harvesting rice for increasing methane emissions in the following season. From this viewpoint, it is requested to report management of rice straw after every harvest more quantitatively in detail in the Method section. It is required to provide the amount of rice straw (and preferably that of stubbles and roots) returned to the fields from previous harvest, because it is essential to discuss the increase in methane emissions. Otherwise, it is vague to discuss the emission pattern in Discussion.

Data analysis:
○ The statistical analysis for judging the differences in methane emissions among the seasons is insufficient, because no statistical analysis was made for the data in Figure 1. As a result, it is difficult to conclude the differences in methane emissions among the seasons.

Results:
○ In this section, the results of experiment should be simply presented. Information of previous studies and discussion with them should be presented in Introduction or Discussion sections, respectively. From this, the sentences in Line 1–6 of ‘Emission level’ part and in Line 1–11 of ‘Emission pattern’ part should be moved.

Data presentation:
○ The amounts of total seasonal methane emission should be numerically presented, at least those of five-year average for each crop with the values of interannual variation.

Discussion:
○ There is fundamental lack of discussion with referring to previous studies by other researches who reported methane emissions from paddy fields. A sweeping revision is necessary in this section.

In addition, some minor comments are listed below:
1. Throughout the manuscript, the term ‘natural flood’ or ‘annual flood’ should be corrected to ‘fallow flood’ because it is confusing. ‘After natural (annual) flood’ can be ‘during the fallow flood period after harvesting the 3rd crop’.

2. Abstract, Line 2: The statement that ‘these emissions are not well studied’ is incorrect. A number of field measurements for methane emissions from paddy fields in the Mekong Delta have been published, such as Vo et al., 2018 (already cited in this paper), and references cited in the paper.

3. Introduction, 1st paragraph, Line 9: The statement that ‘this has not been well studied’ is incorrect. IPCC Guidelines provides the quantitative effects of rice straw incorporation on increasing methane emissions as a scaling factor based on a number of field measurements including those in the Mekong Delta.

4. Introduction, 3rd paragraph, Lines 6–8: The reference that shows effectiveness of the strategy should be cited.

5. Methods, Site description: It is suggested to report the type of soil and its characteristics, because the information is essential for discussing the intensity of methane emissions from paddy fields and is not presented in the previous paper. I would suggest to report, at least,
soil texture, organic carbon content, and pH, all of which are recognized as the major factors controlling methane emissions.

6. Figures 1 and 2: The period of data ‘Flood’ is confusing. It is recommended to correct it with ‘Fallow flood’.

7. Results, Emission level, Lines 9–11: The emission level doubled in the 2nd crop, and tripled in the 3rd crop, compared with that in the 1st crop, then reset after the fallow flood. Same correction should be made at Discussion, Emission pattern, Lines 1–3.

8. Results, Emission level, Lines 13–: The total emission during the fallow flood should be higher ...

9. Results, Emission level, Lines 13–15: Why the result was not consistent to the ‘previous’ report. Please discuss it.

10. Results, Emission pattern, Lines 1–11: This statement is not the results in this study. Therefore, it should be moved to Discussion. Also, the difference of data in ‘previous’ study and this one should be clarified. Understanding from the ‘previous’ paper (Oda & Chiem, 2019), the ‘previous’ study reported the results of experiments during 2016 and 2017, whereas this study during 2011 and 2016. If it is correct, using the term ‘previous’ is not appropriate.

11. Discussion, 2nd paragraph, Line 6: no methane emission -> little methane emission

Is the work clearly and accurately presented and does it cite the current literature?
No

Is the study design appropriate and is the work technically sound?
Yes

Are sufficient details of methods and analysis provided to allow replication by others?
No

If applicable, is the statistical analysis and its interpretation appropriate?
No

Are all the source data underlying the results available to ensure full reproducibility?
Partly

Are the conclusions drawn adequately supported by the results?
Partly

Competing Interests: No competing interests were disclosed.

Reviewer Expertise: biogeochemistry, soil sciences
I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 21 Feb 2020

Masato Oda, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

Thank you for deeply considering our manuscript. We considering your helpful comments and improved the manuscript. However, we are afraid that adopting the term "fallow flood" is not right in case of the Mekong Delta triple cropping rice. In addition, we think the matter of writing style is not constructive because that is largely affected by the background of the main journal we have read. Finally, we are glad to have helpful comments from you. The details of our response are as follows.

Introduction:
• Background (the need for this study) and objectives of the study should be clearly presented. Why did you study methane emissions from paddy fields? What gaps of knowledge did you try to approach? What are the objectives of this study?
*As you mention "there are very few studies that reported methane emissions from triple rice cropping." That is the reason. We described more clearly the aim of the study.

Methods:
• The amount of rice straw
*They were added.

Data analysis:
• No statistical analysis was made for the data in Figure 1.
*You mention the significant tests, don't you? Now, that is no longer recommended; instead, 95% confidential interval is recommended (https://www.nature.com/articles/d41586-019-00857-9). That can be known from the SD and the n. However, we found that the figure is needed correction of the way of calculation of the mean (each crop has three replications but means should be calculated by year, and the n should be changed from 15 to 5). In addition, the error bars were not SD but were SE. We corrected the figure and show the 95% confidential interval (CI). We deeply thank that you give us a chance to correct the error bars.

Results:
• In this section, the results of experiment should be simply presented. Information of previous studies and discussion with them should be presented in Introduction or Discussion sections, respectively. From this, the sentences in Line 1–6 of ‘Emission level’ part and in Line 1–11 of ‘Emission pattern’ part should be moved.
*This is a matter of writing style. The consideration of the values using citations is common in the results section.

Data presentation:
• The amounts of total seasonal methane emission should be numerically presented, at
least those of five-year average for each crop with the values of interannual variation. *We showed them as a range, but we changed that as each average.

Discussion:
• There is fundamental lack of discussion with referring to previous studies by other researches who reported methane emissions from paddy fields. A sweeping revision is necessary in this section.
*This is a matter of writing style. We cited the studies in the introduction section. As you know, they are few.

In addition, some minor comments are listed below:
1. Throughout the manuscript, the term ‘natural flood’ or ‘annual flood’ should be corrected to ‘fallow flood’ because it is confusing. ‘After natural (annual) flood’ can be ‘during the fallow flood period after harvesting the 3rd crop’.
*There is no fallow flood. We show the condition by describing the cropping days and the intervals in the manuscript.

2. Abstract, Line 2: The statement that ‘these emissions are not well studied’ is incorrect. A number of field measurements for methane emissions from paddy fields in the Mekong Delta have been published, such as Vo et al., 2018 (already cited in this paper), and references cited in the paper.
*We cited the description “not well studied” of Vo et al. The situation has not changed after a year.

3. Introduction, 1st paragraph, Line 9: The statement that ‘this has not been well studied’ is incorrect. IPCC Guidelines provides the quantitative effects of rice straw incorporation on increasing methane emissions as a scaling factor based on a number of field measurements including those in the Mekong Delta.
*See above. We think this kind of rebuttal is not constructive.

4. Introduction, 3rd paragraph, Lines 6–8: The reference that shows effectiveness of the strategy should be cited.
*This is a matter of writing style. Showing the main finding of the work at the end of the introduction section is common.

5. Methods, Site description: It is suggested to report the type of soil and its characteristics, because the information is essential for discussing the intensity of methane emissions from paddy fields and is not presented in the previous paper. I would suggest to report, at least, soil texture, organic carbon content, and pH, all of which are recognized as the major factors controlling methane emissions.
*The details of the soil properties will be published in another paper. That is the reason why we don't describe the details. We think this kind of problem that comes from closed science should be diminished in the future.

6. Figures 1 and 2: The period of data ‘Flood’ is confusing. It is recommended to correct it with ‘Fallow flood’.
*We think the word “Fallow flood” imagines a fallow paddy with ponding water. The paddy
in the Mekong Delta is really a flood, a natural disaster.

7. Results, Emission level, Lines 9–11: The emission level doubled in the 2nd crop, and tripled in the 3rd crop, compared with that in the 1st crop, then reset after the fallow flood. Same correction should be made at Discussion, Emission pattern, Lines 1–3.
*You understood correctly without the phrase, “compared with that in the 1st crop”. Flood is not fallow. We think this kind of rebuttal is not constructive.

8. Results, Emission level, Lines 13–: The total emission during the fallow flood should be higher ...
*We cannot agree to use the term.

9. Results, Emission level, Lines 13–15: Why the result was not consistent to the ‘previous’ report. Please discuss it.
*That is in the discussions section. The reset of emission levels after the annual flood means that the rice straw is decomposed without methanogenesis in water because the water includes dissolved oxygen.

10. Results, Emission pattern, Lines 1–11: This statement is not the results in this study. Therefore, it should be moved to Discussion. Also, the difference of data in ‘previous’ study and this one should be clarified.
*Generally, “what the data are” is describes in the results section; instead “what the data meaning” is describes in the discussions sections. According to these criteria, Lines 1-11 is suitable for the results section.

Understanding from the ‘previous’ paper (Oda & Chiem, 2019), the ‘previous’ study reported the results of experiments during 2016 and 2017, whereas this study during 2011 and 2016. If it is correct, using the term ‘previous’ is not appropriate.
*Only published studies can cite in the paper. They are called previous studies, not future studies. We think this kind of rebuttal is not constructive.

11. Discussion, 2nd paragraph, Line 6: no methane emission -> little methane emission
*Theoretically and practically "no" but we follow your recommendation for avoiding unconstructive rebuttal. Thank you.

Competing Interests: No competing interests were disclosed.

I still have concerns about the accuracy of the methodology applied for this work since the result is double the maximum value given by prior studies conducted in the same region. Though the author is convinced that extremely high CH$_4$ is usual in the studied areas but no scientific evidence is shown in context.

Furthermore, the suggestion given by the authors on the decomposing rice straw in flooding field may not be feasible due to a lower gain of the farmers. The authors are convinced that the yield in the tripled crop is low, and the farmers will have much more profit by practising organic farming. This discussion is out of the ring because there is no evidence on rice yield, and organic farming is out of the scope of this work.

Is the work clearly and accurately presented and does it cite the current literature?
Partly

I confirm that I have read this submission and believe that I have an appropriate level of expertise to state that I do not consider it to be of an acceptable scientific standard, for reasons outlined above.

Author Response 12 Feb 2020

Masato Oda, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

1) Methodology
We followed the standard method so replication by others is capable. As you know, to say
overestimate requires grounds; however, data for methane emission in triple cropping rice is little. Note conditions of the reference we indicate are milder than that of the present study. We think the discussion should start waiting for more data.

Importantly, the theme of this brief report is not the emission levels but is the pattern, especially the role of the flood period reducing methane emission. They are not affected by whether we overestimated or underestimated.

2) Discussions
We guess that you might be confusing the personal response and the manuscript because of the system. That is actually “out of the ring”.

We hope you agree with the above explanations.

Author Response 26 Feb 2020

**Masato Oda**, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

We found an example of high emission in Japan ([https://www.naro.affrc.go.jp/org/warc/research_results/skk_seika/h06/94017-z1.jpg](https://www.naro.affrc.go.jp/org/warc/research_results/skk_seika/h06/94017-z1.jpg)). The total amount roughly estimated about 2000 kg CH4 ha-1 crop-1. The result obtained under the condition of 5 Mg of wheat straw and 6 Mg of rice straw. Wheat straw is rapidly decomposed than rice straw. The fresh rice straw in the Mekon Delta triple-cropping rice is considered the middle of those organic materials. We added the information of the quantity of applied rice straw to the revised manuscript. That is about 9 Mg per crop. We think this additional information provides enough reason to understand the high emission in our results.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.
order to explain this study is a representative.

Method:
○ Site description should be more clear, such as, what about the field practices of the farmer on their fields? Were the three observed fields similar in these practices? What about the water management in the fields? The author said the fields was continuously flooding, but how about water level/ regime in three observed fields? How about straw management? What about the height of stubble for each season? How was about fertilization?...

○ Methane measurement: The author said the closed chamber method described by Oda & Chien, 2019. However, a brief description should be added. What time of the day were GAS samples take? How was CH$_4$ calculated?

○ Statistical analysis: A one-way ANOVA should be analysed to compare the means among season?

Discussion:
○ The authors just explained the difference of CH$_4$ emission among seasons was due to straw incorporation into the soil. However, I did not see any information on straw incorporation in the observed fields (as above commented). Other factors such as rice varieties, weather, fertilization... should be discussed. In this case, these factors differed among seasons, why did only straw incorporation influence on CH$_4$ emissions?

Conclusion:
○ As above commented, the conclusion on CH$_4$ emission increase being due to straw incorporation is not clear.

Is the work clearly and accurately presented and does it cite the current literature?

Author Response 05 Nov 2019

Masato Oda, Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

Thank you very much for giving valuable comments.

1. Introduction: a general information in order to explain this study is a representative
Thank you. We added.

2. Methods
2-1. Site description:
The sentence was improved to clarify that the present study was an observation of typical farmer's paddies mentioned in the introduction (including rice straw treatment).

2-2. Farmers practices:
Thank you. We added the reference. The height of the stubble is about 30 cm. The daily average water levels were monitored with water level loggers at the corner of the fields; the average levels were 2.0 cm (−0.6 to 6.1 cm) until drained (the data will be published in another paper).

2-3. Methane measurement:
Thank you. We added.

3. Statistical analysis:
Figure 1 is clear enough to omit ANOVA (see the standard deviation (not SE)).

4. Discussion:
The information on straw incorporation in the observed fields is mentioned in the introduction. Rice straw incorporation enhances methane emission. We added a referred to our previous study that is a kind of short review of the effect of straw incorporation.

Competing Interests: No competing interests were disclosed.
The idea of estimating methane emissions from rice paddy fields is not novel. Many publications, including those conducted in SE Asia, have been widely accepted, such that collected and reported in the 1996 IPCC Guidelines for National Greenhouse Gas Inventories: Reference Manual. The study on triple rice cropping in the Mekong River Delta is quite interesting since few studies carried on such the cropping system, but usually estimating the total flux based upon one single cropping experiment.

My first significant concern in this work is involved with the methodology of methane sampling and analysis. The closed chamber method used in this study (Oda and Chiem, 2019) had not yet been validated with other traditional closed chamber studies. Furthermore, methane emission using this method seems to return significantly higher methane emissions compared to those emissions reported worldwide in the IPCC report. Since very much high emission rates can result in significantly overestimating methane emissions from the SE Asia region, I suggest the authors carefully discuss the reliability of the proposed method in comparison to the traditional method.

My last concern is on the suggestions given by the authors. They claim that decomposing rice straw in paddy surface-water (nonrice period) is an effective method to reduce methane emissions. This suggestion is not conforming to the fact that the wetland system is a significant source of methane emission. I think the author could mean lower methane emission during the nonrice flooding period, but the conclusion written in the manuscript is not clear that way. Although, I think the conclusion given by the authors is not feasible since promoting long-term nonrice flooding instead of rice cropping could mean lower rice yield.

Is the work clearly and accurately presented and does it cite the current literature?
Yes

Is the study design appropriate and is the work technically sound?
Yes

Are sufficient details of methods and analysis provided to allow replication by others?
No

If applicable, is the statistical analysis and its interpretation appropriate?
Not applicable

Are all the source data underlying the results available to ensure full reproducibility?
No

Are the conclusions drawn adequately supported by the results?
Partly

**Competing Interests:** No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 05 Nov 2019

**Masato Oda,** Japan International Research Center for Agricultural Sciences, Tsukuba, Japan

Thank you for giving valuable comments for improving our manuscript.

1. The methodology of methane sampling and analysis.
   Our methodology is the traditional method and there are high emission data in An Giang province. The water management conditions are better than our site because of the full-dike system. Thus, we think our data are reliable. We added the explanations.

2. Suggestion by authors
   We agree with you that the wetland system is a significant source of methane emission. We also agree with you that the methane emission in the paddy field is extremely high compared to the simple wetland. Our finding is that the cause of the high emission in the paddy field is the incorporation of rice straws. The recent spread of combine harvesting decreases the need for rice straw burning. The methane emission will increase much more. Therefore, decreasing the methane emission of the paddy field to the levels of the simple wetland is still significant according to the data. Our suggestion is directly led by the results of the present study; although there are many other indirect options.

For the yield of rice, we think by the profit. A recent study reported that the profit of triple rice is only 6% higher than double cropping († *Environ Manage.* 2018). However, utilizing rice straw enables organic farming and that brings much profit by the high unit price. We are trying to establish cultivation practice. Furthermore, using the ratooning triple cropping is also possible.
