Abstract
Background: Global arterial hypertension (HTA) has increased by 90% over the last four decades, and has increased by 1.6% in Peru over the previous four years. This study involved a network analysis of depressive symptomatology in Peruvian patients with HTA using network estimation.

Method: A representative cross-sectional study at the national level, using secondary data from 2019 Demographic and Family Health Survey (ENDES) was performed. The sample used included men and women of age over 17 years diagnosed with HTA and were able to respond to Patient Health Questionnaire-9 (PHQ-9).

Results: The symptoms of depressive mood (bridging force and centrality) and energy fatigue or loss (bridge centrality) play an essential role in the network structure, as does the feeling of uselessness in terms of closeness and intermediation.

Conclusion: The study highlighted the symptoms related to depressive mood and energy fatigue or loss as bridging symptoms, which could trigger a depressive episode in patients diagnosed with HTA.

Keywords
Hypertension, Depression, Mental Health, Health Surveys, Peru
Introduction

Diagnoses of arterial hypertension (HTA) among other chronic non-communicable diseases are common. It necessarily requires a change of lifestyle that favors the adherence to pharmacological and psychological treatments, to reduce the development of cardiovascular diseases or psychological problems which complicates the patient’s health condition. An international study based on various surveys and reviews from 200 countries indicated that HTA cases worldwide have increased by 90% over the last four decades, with issues mostly identified in low- and middle-income countries. In Peru, the prevalence of HTA has increased in recent years: 2016 (8.6%), 2017 (8.7%), 2018 (9.5%) and 2019 (10.2%). This increase is due to a rise in the population of older people and various lifestyle factors (such as food, minimal physical activity, alcohol consumption, among others). There is also evidence that patients with HTA have a higher incidence of emotional disorders, mainly depressive symptomatology (anxiety or stress), which interferes with their clinical treatment, leading to poor prognosis (not following the doctor’s instructions regarding medicines, minimal personal care) and preventing the acquisition of desirable behaviors to improve their quality of life. A recent study in the Peruvian population indicated that depressive symptoms are most likely to occur in the first year of diagnosis of hypertension. This reinforces the importance of considering evaluation by mental health professionals in improving primary care in persons diagnosed with HTA in Peru.

Several studies have indicated that clinical interventions should primarily focus on depressive patients with HTA. Patients diagnose with HTA normally experience negative emotions due to the fact that they have to consume the drugs prescribed for treatment for the rest of their lives or for a very long period, these emotions are more powerful in situations where their condition is severe, and may generate feelings of loss of control or fear of failure, thus making it more likely that those with HTA condition can develop some emotional disturbances. These emotions are also related to the economic expenses involved in treatment (especially in low and middle-income countries) and the decrease in social interaction with friends or family. Ignoring negative emotions may result in physical disorders. These are likely to decrease adherence to treatments where psychological support is needed, especially the ones associated with risky behaviors such as alcohol consumption.

Therefore, the research aimed to explore the network dynamics of depressive symptomatology in Peruvian adults with arterial hypertension from a network analysis approach, which allows a broad understanding of the interactions and the bridges of connection between the depressive symptoms and the study population.

Methods

A secondary cross-sectional study was conducted based on data from ENDES 2019, which is a national representative survey that collects information on chronic non-communicable diseases and gives access to diagnostic and treatment services in Peru. ENDES design includes a two-stage random sampling technique, differentiated for rural and urban areas. In rural areas, the primary sampling units were groups of 500–2000 individuals and the secondary sampling units were the households within each of these groups. On the other hand, in urban areas, the sampling units consisted of blocks or groups of blocks with more than 2,000 individuals and an average of 140 households, and the secondary sampling units were the same as in rural settings from 36,760 sampled households, 34971 persons aged 15 and older were surveyed with the Health questionnaire. Details of data sampling, processing and collection are contained in the ENDES technical report produced by the National Institute of Statistics and Data Processing (INEI).

Our sample included men and women over the age of 17 diagnosed with HTA. The diagnostic criteria for HTA were those with systolic blood pressure greater than and/or equal to 140 mmHg and/or a diastolic blood pressure greater than and/or equal to 90 mmHg, and had completed the Patient Health Questionnaire (PHQ-9). Exclusion criteria were those who met the diagnostic criteria for hypertension, or did not report any blood pressure measurements, or who omitted any PHQ-9 questions. This allows evaluation of each of the nine DSM-IV depression criteria. PHQ-9 has four response options (0 = nothing at all, 1 = several days, 2 = more than half of days, and 3 = almost every day) and assesses the presence of depressive symptomatology in the last two weeks, the overall response score is in the range of 0 to 27.

Sample

A total of 2915 participants were included in this study, of whom 1106 (37.94%) were male, and 1809 (63.06%) were female. The mean age was 57.9 years (standard deviation: 16.9), with 1456 (49.88%) being older adults (55 years old and over). Of these, 1144 (39.24%) had completed primary education, 844 (28.95%) secondary, 637 (21.75%) higher and 290 (9.94%) did not answer. Regarding the participants native language, 2106 (72.24%) indicated Spanish, 688 (23.6%) Quechua and 121 (4.16%) a different native language.

Data analysis

For the analysis of the data, the graph package version 1.6.5 was used in the statistical software R version 4.0.3, which allows estimation of a Gaussian chart model (GGM) of a regularized partial correlation network to model the interaction between the components of PHQ-9 as autonomous entities, which are represented as circles, called “nodes”. Nodes are connected by lines, called “borders.” Borders in GGM can be understood as conditional dependency relationships between elements. If two items are connected to the resulting network, they are dependent after all other items are adjusted. This analysis presents statistical coefficients of effect size (≤ 0.1 = small; > 0.1 to < 0.5 = moderate; ≥ 0.5 = large) to determine network connections. The precision of the edge weights was estimated to provide greater stability to the results, with a precision of 95% of the confidence intervals through Bootstrapping of 5000 samples around each edge in the network. Also considered were the most commonly used...
centrality indices in psychological networks: force, proximity, intermediation.

Ethical considerations
The investigation did not require the approval of an ethics committee because it only involved the analysis of secondary data obtained from a public and open source, which does not require the identification of the participants and maintains the anonymity of the participants.

Results
In Table 1, the mean scores for each item of the PHQ-9 are shown. This shows that people with arterial hypertension have a higher level of “Depressed mood”. The item also reports that there is a more significant measure of force in terms of other depressive symptoms. Another essential item on the web was Tired or little energy. The elements of lower centrality were “Moving/restless” and “Appetite change”.

Figure 1 shows the network chart of PHQ-9 in Peruvian adults with arterial hypertension, where most of the elements are positively associated with a total of 32 possible edges, in which the highest magnitude associations are found with “Moving/restless” (PH8) and “Suicidal thoughts” (PH9). Also highlighted is the relationships between “Moving/restless” (PH8) “Interest loss” (PH1) and “Depressed mood” (PH2), and the connection of “Feelings of worthlessness” (PH6) and “Trouble concentrating” (PH7). Other measures of centrality

Figure 1. Network analysis of PHQ-9.
have highlighted greater closeness (1.57) and brokering (1.12) in reagent 6. Figure 2 shows the PHQ-9 network estimated border weight confidence intervals.

Regarding the accuracy of network connection magnitudes calculated by Bootstrap analysis, the analysis indicates that there is a high precision with the dependent intervals of the evaluated network.

**Discussion**

This research aimed to explore the dynamics of depression symptoms in adults having Pulmonary arterial hypertension (PAH). This study is the first to use network analysis for PHQ-9 in the Latin American region such as Peru, although several researches have considered network analysis for psychopathological symptoms which may be up to 13 items. Several network trainings on depression symptoms have been evaluated using diverse clinical samples such as chronic pain, depression, bipolar disorder, cancer, but it had been assumed that network analysis has not been performed on Spanish speaking individuals with HTA. Therefore, the importance of identifying the deduced components such as chronic pain, depression, bipolar, disorder, and cancer with a greater focus on evaluating would make it possible to strengthen clinical effectiveness for future interventions in patients diagnosed with HTA. This would be considered only to highlight the strength of the node as the main centeredness index due to its stability. In this sense, the results revealed that the elements with the most centrality are the items of “depressive mood” and “fatigue or energy loss”, this indication may suggest that these symptoms are probably more prevalent in adults diagnosed with HTA. The results are consistent with the McWilliams et al.’s network study in a sample of patients with chronic pain, which indicated the importance of such symptoms. Other longitudinal network studies have also reinforced the centrality of the “depressed state” symptom. Furthermore, a recent systematic study of psychopathological networks also reported transversal and longitudinal studies of depressive and anxious symptomatology, where the depressive mood symptom has greater network centrality. Therefore, health professionals may consider these symptoms as being

![Figure 2. PHQ-9 network estimated border weight confidence intervals.](image)
These findings are similar to previous PHQ-9 network studies in cancer patients, which indicate a greater centrality in reagent 4 (energy loss), which may suggest an indirect relationship of this symptom in people with an irreversible chronic disease.

Conclusions

In conclusion, the most central reagents in the network (2 and 4) with the most connections report a moderate relationship and are relatively close to the system. These network findings suggest possible routes of greater concentration and dynamism in the process of depressive symptomatology that at a higher level and prevalence, it is more likely to activate the interactive development of the various symptoms of PHQ-9, which may even lead to a depressive episode. Those reagents could have a more significant influence on the components with greater online covariance such as “Psychomotor issues,” “suicidal ideation,” and “anhedonia.” Therefore, the results will contribute to developing personalized treatments aimed at patients with specific depressive symptoms have also been diagnosed with HTA.

However, the research has the following limitations; for example, the study is cross-sectional, which does not allow inference of whether a given node is caused or caused by another node to which it is connected, considering that they are non-directed networks. Another point is the selected small sample of a national survey, which also does not allow for generalization of the results to other patients with physical disorders.

In this paper, Cristian Ramos-Vera and colleagues present the findings of network analysis of symptoms of depression in adults with arterial hypertension in Peru. This is a secondary data analysis of a nationally representative survey: ENDES 2019. Very few studies have applied network analysis in the field of mood disorders, especially for co-morbid depression. This is quite a unique study for which we would like to congratulate the authors. However, there are some issues related to methodology, presentation of results, and discussion of limitations which need to be addressed by the authors.

Abstract

1. Background: The first word should be edited to “Globally, arterial hypertension...” instead of “Global arterial hypertension...”. The salience of depression as a comorbidity among people with arterial hypertension needs to be highlighted. Please mention the rationale for using network analysis.

2. Methods: The authors need to clarify the sample included in the study, particularly that: 1) it is a sub-sample (people with arterial hypertension) from the ENDES 2019 dataset, 2) clarify if only those who had ‘complete PHQ-9 questionnaires’ were included.

3. Results: The authors have used terms such as bridging force/ bridge centrality, closeness, and intermediation in the abstract, which are different from the corresponding terms in the manuscript. The authors need to use uniform and standard terminology throughout the paper. These results need to also include the corresponding coefficients for the results.

4. Conclusion: The conclusion reads like results. The interpretation of the results and its implications should be included.
Introduction
1. The authors need to describe how common is depression among people with a diagnosis of arterial hypertension in this section.

2. The appropriate abbreviation for Arterial Hypertension would be AHT or AH. It is not clear why HTA is used.

3. Referring to the sentence - “This increase is due to... such as food” – the type of food needs to be included to suggest poor eating habits.

4. Referring to the sentence – “There is also evidence that patients with HTA have a higher incidence of emotional disorders” – please include how much higher and include appropriate reference.

5. In the same sentence “... mainly depressive symptomatology (anxiety or stress)” – the use of parenthesis is confusing. Perhaps the authors mean “...depressive symptomatology, anxiety and stress”.

6. The sentence “Ignoring negative emotions may result in physical disorders.” – This requires appropriate citation and some further explanation.

7. The rationale for undertaking network analysis and the need to explore network dynamics for symptoms of depression in individuals with hypertension needs to be clearly explained.

8. In the last paragraph of the introduction, the terms used are ‘interactions’ and ‘bridges of connections,’ which are different than the terms used in the abstract earlier and the methods section later (refer to comment # 3 in the section on abstract). As this is a new field, it is important to clearly define the key terms preferably using a box.

Methods
1. Brief information about ENDES dataset, including the disorders screened/diagnosed for the sample, particularly how mental health problems were screened/diagnosed need to be described. Please provide the reference for this study as well.

2. The sentence describing the sampling, “On the other hand, in urban areas... with the Health questionnaire” is confusing. Perhaps a full stop was meant to be included before “from 36,760 sampled households,“.

3. The authors might have missed to add “did not” in the sentence,“ Exclusion criteria were those who (did not) me(e)it the diagnostic criteria for hypertension, or did not report any blood pressure measurements, or who omitted any PHQ-9 questions.

4. Please provide the flow chart for sample selection. It is particularly important to provide the details regarding the differences between those included and excluded in the analysis. The details related to socio-demographic indicators, severity of hypertension and PHQ-9 scores should at least be included.

5. Missing data should be reported, and especially how it was handled should be described,
along with how this is likely to influence the results, if at all.

6. The commonly used term to describe the connection between nodes is ‘edges.’\(^1\) It is not clear why the authors have used the term ‘border.’

7. Bringmann et al. have used the terms degree and strength centrality, betweenness and closeness centrality to describe centrality indices. Authors have cited this paper (reference #12)\(^2\). Please clarify why the terms force, proximity, and intermediation are used by the authors while they cite the above-mentioned paper.

Results

1. For a network with 9 nodes, the possible number of edges is \(\frac{n*(n-1)}{2}\), i.e., \(\frac{9*8}{2}=36\). Not clear why it is mentioned ‘32 possible edges.’

2. It is desirable to have a table which includes PHQ-9 scores for the sample, mean with standard deviation, and proportion of sample that is moderately/severely depressed. This could be disaggregated by age, sex, hypertension, socio-economic status and other independent variables.

3. Please provide partial correlation matrix for all PHQ-9 items.

4. The findings related to only strength centrality are presented in table 1. Please also include the findings pertaining to betweenness and closeness centrality.

5. Please clarify the meaning of negative sign in strength column.

6. Please consider presenting the findings separately for those without depression and those with depression (PHQ-9>5). Similarly present the findings disaggregated by sex and severity of depression.

7. Please explain non-inclusion of socio-demographic factors and hypertension in the network analysis. Factors others than the symptoms of depression are included in the analysis to see how they influence each other.

8. Is it possible to present predictability analysis as suggested by Contreras et al.\(^1\)

Discussion and Conclusion

1. Greater centrality for PHQ-6 needs to be further discussed. PHQ-8 and PHQ-9 are clinically very significant but have low centrality measures. This also needs to be discussed.

2. It will be good to discuss the findings related to various centrality indices in detail.

3. The discussion could benefit from including more critical analysis of how their findings differ from other studies and the implications, therefore. For e.g., McWilliams et al (ref 15 in the paper) found that in addition to the depressed mood and tiredness/low energy, two other symptoms - loss of interest and trouble concentrating also have high centrality, which is in contrast with the authors findings. The discussion could explore potential reasons for this and implications.
4. The first paragraph of conclusion appears to fit better with the discussion section.

5. The authors should elaborate and include reference for the statement, “Those reagents could have a more significant influence on the components with greater online covariance such as “Psychomotor issues,” “suicidal ideation,” and “anhedonia.”

6. Referring to sentence, “Therefore, the results will contribute to... have also been diagnosed with HTA.” This statement needs to re-phrased for better readability.

7. There are several issues related to use to centrality indices and are discussed in detail by Bringmann et al. They have recommended to use these measures with considerable care. Authors need to include a paragraph to discuss this and highlight the limitation of using centrality indices.

8. It will be desirable to provide R Script as an appendix. This will ensure the reproducibility of the results.

**Author Response 22 Mar 2021**

**Roseline Ogundokun, Landmark University Omu Aran, Omu Aran, Nigeria**

**Title.** The authors describe the population studied as “Peruvian adults”. However, the sample used included 17-year-olds, and in Peru only those over 18 are considered adults.

**Response:** It was stated in the article that more than 17 years of age which means from 18 years and above

**Introduction.** “HTA” is the acronym for hipertensión arterial (arterial hypertension in Spanish); it is not applicable in an article published in English. On the other hand, the relationship between depression and arterial hypertension is described; however, it is necessary to analyze other possibilities. For example, depression and chronic anxiety are considered risk factors for the development of high blood pressure, and emotional disturbances might be the adverse effect of some antihypertensive medications.

**Response:** The comment has been attended to.

**Methods.** It should be mentioned that there is a validation of PHQ-9 for the Peruvian population, which was done precisely from ENDES 2019 1 Also, there is an obvious error in the following sentence: “Exclusion criteria were those who met the diagnostic criteria for hypertension.”

**Response:** The comment has been attended to.

**Discussion.** The authors mentioned that “this research aimed to explore the dynamics of depression symptoms in adults having Pulmonary arterial hypertension (PAH).” However, in the rest of the article only arterial hypertension is mentioned, without further specification.

**Response:** The comment has been attended to.

**Conclusions.** It should be mentioned, as a limitation, that the sample did not exclude people with other serious diseases that are usually associated with high blood pressure, and which could also be related to the appearance of depressive manifestations (for example: stroke or chronic kidney disease). Finally, it is not clear how the results of the study can lead to personalized treatments; this part should be better explained by the authors.
Response: The comment has been attended to.

**Competing Interests:** No competing interests were disclosed.

Response: The comment has been attended to

The sentence “Ignoring negative emotions may result in physical disorders.” – This requires appropriate citation and some further explanation.

Response: The comment has been attended to

The rationale for undertaking network analysis and the need to explore network dynamics
for symptoms of depression in individuals with hypertension needs to be clearly explained.

Response: The comment has been attended to

In the last paragraph of the introduction, the terms used are ‘interactions’ and ‘bridges of connections,’ which are different than the terms used in the abstract earlier and the methods section later (refer to comment # 3 in the section on abstract). As this is a new field, it is important to clearly define the key terms preferably using a box.

Response: The comment has been attended to

Methods

Brief information about ENDES dataset, including the disorders screened/diagnosed for the sample, particularly how mental health problems were screened/diagnosed need to be described. Please provide the reference for this study as well.

Response: The comment has been attended to. This has been described in the article and no mental health diagnosis was made. Only those who completed all the PHQ-9 were included.

The sentence describing the sampling, “On the other hand, in urban areas... with the Health questionnaire” is confusing. Perhaps a full stop was meant to be included before “from 36,760 sampled households,”.

Response: The comment has been attended to

The authors might have missed to add “did not” in the sentence,” Exclusion criteria were those who (did not) me(e)t the diagnostic criteria for hypertension, or did not report any blood pressure measurements, or who omitted any PHQ-9 questions.

Response: The comment has been attended to

Please provide the flow chart for sample selection. It is particularly important to provide the details regarding the differences between those included and excluded in the analysis. The details related to socio-demographic indicators, severity of hypertension and PHQ-9 scores should at least be included.

Response: This Has Nothing to do with the study objective and reference was already made to the inclusion and exclusion factors

Missing data should be reported, and especially how it was handled should be described, along with how this is likely to influence the results, if at all. The commonly used term to describe the connection between nodes is ‘edges.’ It is not clear why the authors have used the term ‘border.’

Response: The missing data did not influence the results, because they were only not
reported in relation to the language and grade of studies, whose variables are not in the network analysis.

Bringmann et al. have used the terms degree and strength centrality, betweenness and closeness centrality to describe centrality indices. Authors have cited this paper (reference #12). Please clarify why the terms force, proximity, and intermediation are used by the authors while they cite the above-mentioned paper.

Response: The comment has been attended to

Results
For a network with 9 nodes, the possible number of edges is \((n*(n-1))/2\), i.e., \((9*8)/2=36\). Not clear why it is mentioned ‘32 possible edges.’

Response: The comment has been attended to. This has been corrected to 36 nodes

It is desirable to have a table which includes PHQ-9 scores for the sample, mean with standard deviation, and proportion of sample that is moderately/severely depressed. This could be disaggregated by age, sex, hypertension, socio-economic status and other independent variables.

Response: The analysis does not have sociodemographic purposes for which it is not considered

Please provide partial correlation matrix for all PHQ-9 items.

Response: This is provided in the article already

The findings related to only strength centrality are presented in table 1. Please also include the findings pertaining to betweenness and closeness centrality.

Response: Reference was made on the use of the only measure that reports greater stability, the others do not allow accurate interpretations, especially with high sample data

Please clarify the meaning of negative sign in strength column.

Response: refers to a negative force

Please consider presenting the findings separately for those without depression and those with depression (PHQ-9>5). Similarly present the findings disaggregated by sex and severity of depression.

Response: The purpose was to evaluate according to the total sample, performing by different categoric variables generates a complexity of different results that do not support the study objective, which, according to the sample size, allows generalizing
the symptomatology hypersensitive positivity in priority.

Please explain non-inclusion of socio-demographic factors and hypertension in the network analysis. Factor's others than the symptoms of depression are included in the analysis to see how they influence each other.

Is it possible to present predictability analysis as suggested by Contreras et al.1

Response: This is not possible because it requires Longitudinal Data

Discussion and Conclusion
Greater centrality for PHQ-6 needs to be further discussed. PHQ-8 and PHQ-9 are clinically very significant but have low centrality measures. This also needs to be discussed.

Response: The comment has been attended to.

It will be good to discuss the findings related to various centrality indices in detail.

Response: This was already specified the inclusion of the centrality measures of greatest implication in psychological networks, which must be considered the centrality of force because of its stability.

The discussion could benefit from including more critical analysis of how their findings differ from other studies and the implications, therefore. For e.g., McWilliams et al (ref 15 in the paper) found that in addition to the depressed mood and tiredness/low energy, two other symptoms - loss of interest and trouble concentrating also have high centrality, which is in contrast with the authors findings. The discussion could explore potential reasons for this and implications.

Response: The comment has been attended to.

The first paragraph of conclusion appears to fit better with the discussion section.

Response: The comment has been attended to.

The authors should elaborate and include reference for the statement, “Those reagents could have a more significant influence on the components with greater online covariance such as “Psychomotor issues,” “suicidal ideation,” and “anhedonia.”

Response: The comment has been attended to.

Referring to sentence, “Therefore, the results will contribute to... have also been diagnosed with HTA.” This statement needs to re-phrased for better readability.

Response: The comment has been attended to.
There are several issues related to use to centrality indices and are discussed in detail by Bringmann et al. They have recommended to use these measures with considerable care. Authors need to include a paragraph to discuss this and highlight the limitation of using centrality indices.

**Response: This is already explained in the article**

It will be desirable to provide R Script as an appendix. This will ensure the reproducibility of the results.

**Response: It is not possible because it is part of another study in progress**

**Competing Interests:** No competing interests were disclosed.
