Abstract
Oligodendrocytes wrap multiple lamellae of their membrane, myelin, around axons of the central nervous system (CNS), to improve impulse conduction. Myelin synthesis is specialised and dynamic, responsive to local neuronal excitation. Subtle pathological insults are sufficient to cause significant neuronal metabolic impairment, so myelin preservation is necessary to safeguard neural networks. Multiple sclerosis (MS) is the most prevalent demyelinating disease of the CNS. In MS, inflammatory attacks against myelin, proposed to be autoimmune, cause myelin decay and oligodendrocyte loss, leaving neurons vulnerable. Current therapies target the prominent neuroinflammation but are mostly ineffective in protecting from neurodegeneration and the progressive neurological disability. People with MS have substantially higher levels of extracellular glutamate, the main excitatory neurotransmitter. This impairs cellular homeostasis to cause excitotoxic stress. Large conductance Ca²⁺-activated K⁺ channels (BK channels) could preserve myelin or allow its recovery by protecting cells from the resulting excessive excitability. This review evaluates the role of excitotoxic stress, myelination and BK channels in MS pathology, and explores the hypothesis that BK channel activation could be a therapeutic strategy to protect oligodendrocytes from excitotoxic stress in MS. This could reduce progression of neurological disability if used in parallel to immunomodulatory therapies.

MS is the most prevalent chronic demyelinating disease which affects 2.8 million people worldwide. Its increasing prevalence poses a significant socio-economic burden. The aetiology of the disease is not completely understood, but demyelination pathology predominates alongside inflammation. In demyelinating diseases, like MS, an initial local attack against myelin sheath is proposed to trigger a cascade of neuroinflammatory and degenerative pathways causing damage to oligodendrocytes, myelin, and neurons. This impairs CNS conduction. Other less common demyelinating conditions such as Neuromyelitis optica (Devic’s disease), transverse myelitis, and acute disseminated encephalomyelitis all have an inflammatory component. Demyelinating diseases may also have a genetic cause such as adrenoleukodystrophy, which is a X-linked genetic disorder where mutation in the <i>ABCD1</i> gene causes a defect in the corresponding ABCD1 transporter protein and accumulation of very long chain fatty acids in the brain and spinal cord leading to inflammation in the white matter, cerebral demyelination and neurodegeneration. Fragile X syndrome is a genetic disorder where transcriptional silencing of the <i>FMRI</i> gene leads to loss of the corresponding fragile X mental retardation protein (FMRP). FMRP acts as a RNA transcriptional regulator affecting the function of hundreds of proteins. Demyelination is an under-recognised feature of fragile X syndrome, in model systems FMRP silencing has been found to decrease the degree of myelination.

MS treatments can be classed as disease modifying therapies, (DMTs), to delay progression, or symptom management treatments. Current DMTs are immunomodulatory, with some specifically preventing myelin attack, notably by blocking peripheral immunity. Despite positive outcomes for neuroinflammation, underlying pathology is still not completely targeted (Table 1). B cell directed therapies are amongst the most effective treatments; as these reflect the emerging disease understanding placing memory B cells at the centre of the disease mechanism. Although disability is reduced, neurodegeneration and defects in remyelination and repair still occur. Progression to secondary progressive MS (SPMS) is often not prevented and therapies successful for relapsing remitting MS (RRMS) become ineffective. With the difficulty of finding strategies to prevent neurodegeneration in general and few DMTs for SPMS, new therapeutic approaches need to target underlying demyelination, to date no remyelination strategies have proved effective. This unmet clinical need has led to the development of some diverse approaches using both repurposed drugs and novel therapeutics. Some of the most promising ideas are listed in Table 1.

The aims of this review are: to explain the importance of structurally and functionally intact myelin; to address the current lack of therapies targeting neurodegeneration particularly in MS; to evaluate the role of excitotoxicity in oligodendrocyte pathology and to explore the potential for therapeutic use of large conductance Ca<sup>2+</sup> activated K<sup>+</sup> channel activators to protect oligodendrocytes from excitotoxic stress, ultimately to preserve myelination.

### Oligodendrocytes and myelin in demyelinating disease

Neuronal impulse conduction is formed by action potentials (APs). These are generated from a momentary change in the ionic gradient across the axon membrane that propagates down and is relayed to the next neuron. Repeated and synchronised through billions of neurons, these rapidly transmit

information across the body. In the CNS oligodendrocytes wrap axons with compact lamellae of their membrane myelin sheath\(^\text{19}\). The low capacitance, high lipid content of myelin propagates action potentials (APs) directly onto short unmyelinated 1-μm axolemma segments, nodes of Ranvier. Voltage-gated Na\(^+\) channels concentrate here to integrate a voltage difference so that APs can “skip” myelin internodes through saltatory conduction to increase velocity of impulses. The diameter of myelinated axons positively correlates with conduction velocity\(^\text{20,21}\); while myelin thickness inversely correlates with capacitance\(^\text{22}\). Therefore, myelin provides an energy saving evolutionary adaptation; also because it restricts the number of Na\(^+\)/K\(^+\) ATPases to the nodes, so it decreases the chemical energy ATP required to maintain resting potential\(^\text{19}\). By myelinating larger axons, above ~2 μm in diameter, myelin allows signals to be transmitted fast over a long range\(^\text{19}\).

The brain expends one-fifth of total body energy output, but myelin prevents axons from receiving metabolic support extracellularly, so healthy oligodendrocytes are indispensable for axonal support (Figure 1). Although neurons rely on their own mitochondria to synthesise ATP, these require glial glycolytic products, primarily lactate\(^\text{23}\). Neuronal death can be induced by inhibiting oligodendrocyte glycolysis or neuronal mitochondrial respiration, but not by inhibiting neuronal glycolysis or oligodendrocyte oxidative phosphorylation\(^\text{24}\). It was found that deleting the lactate transporter protein MCT1 impaired axons and caused atrophy\(^\text{25}\). MCT1 being expressed relatively specifically by oligodendrocytes, these results indicate oligodendrocytes are important for healthy neuronal metabolism. However, other studies found that upon electrical stimulation neurons used their own glucose to synthesise energy, which might indicate oligodendrocytes are a primary glycolytic source only for neurons at rest\(^\text{26}\). MCT1 is lost in neurodegenerative diseases like amyotrophic lateral sclerosis, where motor neuron death at the spinal cord indicates impaired axonal lactate supply\(^\text{25}\). Neurons may depend on oligodendrocytes for metabolic support to survive and function properly, but the pathological relationship may cause damage before or separate to evident demyelination.

Metabolic support to axons requires astrocytes, which transfer glycolytic products to neurons through oligodendrocytes (Figure 1). This by way of connexins on astrocytic processes and on oligodendrocytes which co-localise to form gap junctions\(^\text{27}\). Astrocytes have glycogen stores and upon hypoxia or hypoglycaemia glycogen is catabolised into lactate for delivery to neurons\(^\text{28}\). Furthermore, connexins found at paranodes may indicate a cooperation of astrocytes and

Demyelination in multiple sclerosis

Demyelination is the erosion of myelin sheaths, which exposes nerve fibres leading to failure of impulse conduction. It can derive directly from traumatic or ischaemic injury. Alternatively, it originates from attack of myelin related proteins in autoimmune disease. Loss of myelin does not necessarily lead to neuronal death, but overburdens axons by decreasing efficiency of energy homeostasis, making it harder for neurons to meet metabolic demands. Without myelin for saltatory conduction, energy needed to relay impulses increases. This eventually leads to increased functional impairment and susceptibility to further neurodegeneration.

Preserving myelin

Oligodendrocytes are limited in their ability to respond to damage and at least in part depend on replacement by their precursors, OPCs. In the adult CNS, NG2+ cells, which include OPCs and neural progenitors, constitute nearly 9% of white matter. Their migration into sites of injury is crucial for remyelination, whereby myelin regenerates spontaneously around demyelinated axons. Preserving myelin is important because neuroaxonal regeneration is limited. Macrophages have a strong influence, and microglia promote this by clearing myelin debris. Underlying demyelination and inflammation must resolve before new myelin forms. Remyelination may protect axons from inflammation-mediated neurotoxicity and is observed in both acute and chronic lesions, even concomitant to demyelination, and in early MS.

Successful remyelination depends on sufficient OPC pools, their migration and survival, until differentiated into myelinating oligodendrocytes; but this does not guarantee it. In MS, OPCs differentiation may arrest before myelin synthesis completes. Axonal density is higher in remyelinated than chronic demyelinated plaques. However, demyelination may re-occur more frequently in new myelin because newly differentiated oligodendrocytes may produce thinner and shorter sheaths, possibly from external ischaemic factors of the neuroinflammatory environment impairing proper myelination. Additionally, lesion remyelination occurs 20% more often in acute than chronic lesions, so remyelination may inversely correlate with disease progression or age. Therefore, preserving myelin might provide a better neuroprotective strategy than remyelination.

Communication between axons and myelin

About one-third of myelin sheath constitutes proteins that determine myelin architecture. Myelin basic protein (MBP) is a final component added to sheaths, responsible for compaction. MBP localises and draws two adjacent membranes together at clusters, where it forms a dense fibrillary network. This prevents signal dissipation and makes neurons more energy efficient. Downregulation of MBP impairs sheath structure in vivo and knockout decreases axonal calibre. Conversely, 2',3'-Cyclic nucleotide 3'-phosphodiesterase (CNP) regulates cytoplasm quantity within myelin by maintaining actin cytoskeleton. This creates channels and directly counteracts MBP compaction. Working antagonistically, CNP and MBP can adjust these channel systems, possibly to modulate the type and amount of substrate exchange with axons. In mice, knockout of CNP1 and of the functionally similar myelin proteolipid protein caused loss of fibres, of axonal integrity and axonal swelling by impairing neuronal transport. This indicates that intact microstructure is important to preserve local support by oligodendrocytes and that effective conduction depends on this. Indeed, these properties of myelin microstructure can vary to preserve diverse neural networks, to adjust input latencies in nuclei. A latency of about 2 ms remains constant for thalamocortical signals to reach the sensory cortex despite fibres of different lengths. Instead of gross insulation, myelin tunes its microstructure to local axon requirements.

Electrically-silenced axons myelinate inadequately. Maintaining high K+ levels extracellularly reduced myelination by increasing depolarisation duration, so APs are a putative channel.
of communication with oligodendrocytes. Recent advances in electron microscopy and myelin preservation revealed structure of the developed myelin sheath around axons. It is now possible to infer a peri-axonal space, where APs may be relayed by neurotransmitter release. Glutamate is the main excitatory neurotransmitter of the nervous system. Typically, it is released at axon terminals to bind to ligand gated ionotropic receptors found post-synaptically on dendrites. Types of ionotropic receptors are glutamatergic NMDARs, AMPARs and kainate receptors. Upon neurotransmitter binding, of communication with oligodendrocytes. Types of ionotropic receptors are glutamatergic NMDARs, AMPARs and kainate receptors. Upon neurotransmitter binding,
these open voltage-gated channels for selective cation influx, for AP relay. In mature oligodendrocytes, glutamate may be released at the axolemma to affect the inner tongue of myelin sheath.

Glutamate release from synaptic vesicles along axons can stimulate MBP production to promote the insulating properties of myelin. Glutamatergic synapses are a feature of developing OPCs, whereby oligodendrocytes may depend on glutamate signalling for myelination. Activity dependent myelination may promote the migration and differentiation of OPCs. Stimulating the prefrontal cortex resulted in increased OPC migration and myelin thickness only in the optogenetically modified mouse model. This was associated with improved motor skills. Glutamatergic signalling down-regulation may alter myelin thickness because, in mice, reduction of visual stimuli associated with reduced conduction velocity. When tetanus toxin was used to inhibit glutamate release from the synapsosome, Ca^{2+} influx into oligodendrocytes did not occur, supporting mediation by excitatory neurotransmitter release. Although most myelinic ionotropic receptors are removed with differentiation, their use in preserving correct myelination in mature oligodendrocytes might explain the few remaining NMDARs at the myelin sheath also gauge glycolytic delivery in response to axon energy demand. Substrate exchange may be triggered by AMPAR/ NMDAR activation, which induced exosome delivery. Dysregulation of firing frequency would therefore reduce myelin neuronal support (Figure 1). In pathology this activity dependent alteration of myelin architecture may be rendered unresponsive, counterproductive or even toxic to neurons, even before overt demyelination. Modulating this glutamatergic signalling may preserve myelin and neurons.

**Excitotoxic stress**

**Excessive extracellular glutamate**

Excitotoxic stress is caused by excessive or prolonged activation of glutamatergic receptors causing Ca^{2+} overload. This sustains pro-apoptotic pathways involving enzymes and transcription factors like MAPK and NF-xB, which degrade membranes, proteins and intracellular organelles. Increased glutamatergic signalling can be triggered by the energy deficiency from the cellular damage in lesions, mitochondrial dysfunction and oxidative stress. The last involves highly reactive and damaging free radicals: ROS and RNS. These cause mitochondrial membrane damage by lipid peroxidation, which exacerbates cellular burden and glutamatergic signalling. At high levels glutamate is thought to induce oxidative stress by means of blockade of the glutamate/cystine antiporter (XC–Cys/Glu) that prevents uptake of cystine and synthesis of the anti-oxidant glutathione, in a form of cell death termed ferroptosis or oxytosis.

Damage to neurons causes axon swelling, where ion channels including voltage-gated sodium channels are upregulated to attempt compensation for impaired conduction. Excitotoxic damage to myelin may cause this upregulation without necessarily causing overt demyelination. Axon swelling impairs network connectivity in MS, where sustained glutamatergic activation associates significantly with increased neurological disability.

Glutamate is upregulated in MS CSF (p<0.001) and carrying the polymorphism rs794185 that further increases this association with neurodegeneration. The major source of glutamate production is difficult to discern, but evidence suggests neuroinflammation is important. Pro-inflammatory cytokines TNFα and IL-1β cause neurotoxicity by downregulating astrocytic glutamate transporter and glutaminase which accumulates glutamate in the extracellular space. IL-1β but not TNFα are established as significantly upregulated in MS CSF. Immune activation upregulated the cysteine glutamate exchanger on macrophages and microglia and in MS patients. To synthesise important antioxidant glutathione this exchanger releases glutamate extracellularly.

Table 2 describes drugs targeting excitotoxicity in MS, highlighting the still unmet clinical need. These therapies are inadequate clinically because antagonists of glutamatergic pathways can downregulate excitatory CNS conduction, which importantly can cause serious adverse events. Selectivity could be improved by targeting receptor subunits specific to glial cells and that are more permeable to pathological Ca^{2+} accumulation, like NR1 and NR3 NMDAR subunits. Sodium channel blockers provide an alternative means to control excitotoxicity and some benefit has been noted in the more recent clinical trials, but they are poorly tolerated leading to non-compliance.

**Oligodendrocytes are deficient in their response to excitotoxic stress**

Oxidative damage to proteins and lipids is substantially increased in acute demyelinating lesions compared to healthy white matter. Hypertrophic astrocytes and foamy macrophages are able to limit this damage by upregulating antioxidant superoxide dismutase, but not other components of lesion tissue including neurons and oligodendrocytes. Oligodendrocytes have a particularly inefficient antioxidant protection. These have a reduced ability to synthesise glutathione and their death positively correlates with concentration of the highly reactive lipid peroxidation product 4-HNE. Oligodendrocytes are also the main cells that store iron in a balance that is susceptible to conversion to its oxidative divalent form. Their susceptibility to excess glutamate activation specifically is supported by in vitro studies. Only upon inhibition of glutamatergic receptors in oligodendrocytes-only cultures were the apoptotic indicators DNA fragmentation and caspase-3 abolished.

Experimental autoimmune encephalomyelitis (EAE) is an established MS model induced by adoptive transfer of anti-myelin protein T cells. In EAE mice, 60% more of the oligodendrocytes population was preserved with the AMPA/kainate receptor inhibitor NBQX compared with administering phosphate buffered saline (PBS) only, which also improved neurologic impairment score (p<0.01).
AMPAR-mediated Ca\(^{2+}\) influx activates a sustained phosphorylation of ERK1/2 to activate proapoptotic pathways in oligodendrocytes and mitochondrial impairment in a manner similar to ischaemia\(^{62}\). Ca\(^{2+}\)-permeable AMPARs are upregulated only at MS lesions, but not in regions of healthy tissue\(^{89}\), so Ca\(^{2+}\) permeability might indicate upregulation of excitotoxic responses with demyelination. Considering the complex pathological microenvironment of lesions, glutamatergic receptor inhibition alone might not prevent cytotoxicity locally in MS. Pro-inflammatory damage spreads centrifugally from the lesion centre\(^1\), so inhibition might instead prevent spread of excitotoxins.

AMPAR/kainate receptors are mainly expressed on oligodendrocytes soma, while myelin mainly expresses NMDARs\(^{90}\). Excitotoxic stress to myelin can cause decompaction of myelin sheath\(^{90}\), which can impair neuronal metabolism before overt demyelination. Since damaged or degraded myelin sheaths increase neuronal metabolic burden and expose axons to inflammation related toxins, this suggests therapeutically protecting myelin from excitotoxic stress may be neuroprotective in MS. A characteristic feature of MS is a dying back oligodendrogliopathy which, in a similar way to complement activation by direct antibody attack\(^{4}\), might also be caused by activation of catalases and mitochondrial redox damage at myelin processes which retrogradely affects oligodendrocytes.

NMDARs induce weaker Ca\(^{2+}\) currents compared with AMPARs but sustain these for longer\(^{53}\). The small cytosolic compartment of myelin may quickly accumulate Ca\(^{2+}\) concentrations sufficiently high to be toxic. All compartments needed for NMDARs to be functional have been detected with immunoblotting: NR1, NR2 and NR3\(^{90}\). These require activation by both glutamate and its co-agonist glycine. Release of only glutamate from myelinated axolemmas has been established\(^{58}\). The Mg\(^{2+}\) block characteristic of NMDARs can be released by a slight depolarisation\(^{53}\), which may justify the expression of AMPARs on myelin at lower concentrations. Especially because AMPARs inhibitors only partially abolished the Ca\(^{2+}\) current through myelin, but completely at oligodendrocytes soma, while non-selective ionotropic receptor inhibitor completely ablished at both locations\(^{90}\). This suggests a mediating effect by AMPAR.

However, no significant decrease of NMDAR mediated Ca\(^{2+}\) into oligodendrocytes when their inhibitors, NBQX or D-AP5 respectively, were added after ischaemia\(^{91}\). The authors proposed excitotoxicity does not derive directly from glutamatergic Ca\(^{2+}\) influx, but from the resulting K\(^{+}\) and H\(^{+}\) increase.
because the NMDA evoked current correlated with K⁺ increase. The resulting decrease in pH (from K⁺ and from the hypoxic cell) might activate H⁻-gated TRP channels which then caused about 70% of the Ca²⁺ rise⁹. TRP block reduced myelin decompaction, so it is possible these channels are more responsible for the ischaemic excitotoxicity to oligodendrocytes than direct ionotropic receptor activation. Alternatively, the majority of Ca²⁺ may derive from a secondary source, such as from subsequently activated voltage gated calcium channels (VGCCs) or the reversal of the Na⁺/Ca²⁺ exchanger which can occur in conditions of excessive depolarisation⁹.

Dying oligodendrocytes release high levels of Fe²⁺ which directly contributes to oxidative injury to neurons⁸⁹. This accumulates at acute demyelinating lesions, phagocytosed and released through oxidative burst. Ferrous iron, Fe²⁺, is a mediator of the Fenton reaction that synthetises hydroxyl and H₂O₂ radicals⁹. Excitotoxic stress will damage oligodendrocytes, which will in turn release more oxidative stress, although contribution of oligodendrocytes excitotoxicity is still unclear because complex to quantify.

**BK channels reduce excitotoxic stress**

**BK channels**

Large conductance calcium-activated, voltage gated potassium channels (BK channels) are the most diverse within the family of transmembrane protein channels, which also includes small and intermediate K⁺ conductance (SK and IK) channels⁹². These are activated by thresholds of voltage or Ca²⁺ transients and accordingly control membrane potential by mediating efflux of the required amount of hyper-polarising K⁺⁹⁴. They can also be activated by other metal ions such as Mg²⁺, but also by pH, arachidonic acid and nitric oxide. Encoded by the KCNMA1 (or SLO) gene, BK channels constitute a heterodimer of pore-forming α-subunits and a monomer comprising a voltage-sensing and a calcium-sensing module⁹⁴. Ubiquitous, BK channels are overexpressed in regions of high Ca²⁺ concentrations⁹⁵. By mediating K⁺ transients out of cells, BK channels can also regulate K⁺ homeostasis, cell volume, and therefore have various functions including neuronal excitability, smooth muscle relaxation, blood pressure control and electrical tuning of cochlear hair cells⁹⁶.

The highly dynamic physiological properties of BK channels are partly due to the numerous α-subunit splice variants, which makes their translated protein structure highly versatile physiologically. For example, a cysteine-rich 59-amino-acid insert between RCK domains called STREX variant can be added to the C-terminus⁹⁸, resulting in increased sensitivity to activation, inducing higher neuronal firing frequencies. Additionally, BK channels assemble auxiliary subunits, such as β subunits (β1–4)⁹⁸. These can modify activity, including modifying sensitivity to its activators, voltage or Ca²⁺, or by activating protein kinases⁹⁸. Furthermore, the association with γ subunits, which are leucine rich repeat containing proteins, can increase stimulability of the BK channel by decreasing the negative voltage difference threshold⁹⁹. Ultimately, this increases the range of pharmacological applications of these channels.

**BK channels regulate neuronal excitability**

In the CNS, BK channels are abundantly expressed on axons, dendrites, soma and synaptic terminals in widespread CNS regions. Here, these can control the fast phase of after-hyperpolarisation. Additionally, these can control AP output by changing the magnitude and duration of incoming Ca²⁺ spikes at dendrites¹⁰¹. This will determine AP duration and firing frequency¹⁰². BK channels can mediate their activities and their responses specifically for their cellular location and type of neuronal cell by co-localising with functionally distinct VGCCs¹⁰². BK channels have been shown to co-localise with L-/P/Q-, or N-/I-types of VGCCs¹⁰³,¹⁰⁴. Depending on the frequency of basal firing, the BK channels at that neuronal cell will typically provide the opposite effect to modulate and re-set the phase, ultimately to flatten the frequency-current curve and control neuronal excitability. This would occur in a manner similar to hyperpolarisation activated by cyclic nucleotide gated channels, that set the “pacemaker” firing frequency in the brain¹⁰⁵. Overall, studies of BK channels indicate these tune the neuronal signal by amplifying it if weak or reducing it if too strong, rather than stringently enhance inhibition or excitation¹⁰⁶–¹⁰⁸.

BK channels also have an important role in directly mediating neurotransmitter release, this is supported by their co-localisation to VGCCs with those of the P/Q-type being most frequently observed. This co-localisation occurs predominantly at dendrites where it regulates dendritic spike generation relative to neurotransmitter release¹⁰⁹. This is consistent with localisation of the BK α subunits at presynaptic terminals in functionally important axon tracts¹¹⁰. At these locations, BK channels limited the Ca²⁺ mediated neurotransmitter release by decreasing presynaptic APs duration¹¹⁰. Indeed, release of neurotransmitter from vesicles is triggered by Ca²⁺ elevated locally through VGCCs, once the propagated AP reaches the terminal¹¹¹. Typically, BK channels would reduce neurotransmitter release, because these are able to reduce the amplitude of the presynaptic AP. An important demonstration of this is the effect on neurotransmitter release by CA3 hippocampal neurons and associated APs upon addition of BK channel blockers. The resulting spontaneous EPSCs increased in amplitude and frequency¹¹². This inhibition ultimately reduces release of glutamate, but does not occur for inhibitory neurotransmitter GABA¹¹². Therefore, BK channels are key to avert overexcitation of the post synaptic neuron.

**Mediators of excitotoxic stress**

Physiologically, BK channels can prevent too much neurotransmitter from causing excessive depolarisation and Ca²⁺ accumulation post-synaptically. In mice where acute focal cerebral ischemia was induced by middle cerebral artery occlusion, the neurological symptoms were significantly higher with
knockout of the BK α subunit compared to wild type\textsuperscript{113}. This may imply glutamate-induced oxidative stress, and consequences for acute and chronic neurodegeneration. This negative feedback by BK channels might only occur if propagated APs are high enough to induce levels of intracellular Ca\textsuperscript{2+} and neurotransmitter similar to those observed in pathological conditions. For example, only upon addition of 4-AP, a non-specific inhibitor of voltage gated K\textsuperscript{+} channels, were BK channels activated to decrease AP amplitude post-synaptically and decrease neurotransmitter release\textsuperscript{114}. No amplified repolarisation or reduced neurotransmitter release by BK channels was observed without 4-AP. This is specific to excitatory neurotransmitter release, because a concentration dependent reduction in ischaemia mediated by NMDAR correlated with increased opening of BK channels by the activator NS1619\textsuperscript{115}. By creating a negative feedback control to disproportionate neurotransmitter release, BK channels may be an emergency break to prevent hyperexcitability and subsequent toxicity.

**Activating BK channels to protect oligodendrocytes**

Much of the available evidence relates to neurons, but if there is a functional link between the role of BK channels and oligodendrocytes in mediating this excitotoxic stress, targeting this could possibly provide an avenue for disease modifying therapy in MS.

Although big conductance, calcium-activated potassium (BKCa) channels, notably KCNMB4 isoforms are neuronally expressed\textsuperscript{116}, it is evident that KCNMB4 is also present and differentially expressed by oligodendrocytes\textsuperscript{117,118}. OPCs were associated with high expression of KCNMA1 and KCNMB2 (Figure 3A, 3B), at a time when they express many ion channels perhaps as part of the pre-myelination glial-neuronal synapse\textsuperscript{119}. However, it is evident that oligodendrocyte maturation and myelination was associated with their relative loss and the upregulation of the KCNMB4 BK isoform (Figure 3A, 3B). In addition transcriptomic expression of KCNMA1 and KCNMB4 in NG2\textsuperscript{+} cells has been found\textsuperscript{120}.

Human KCNMB4 expression increases as OPCs mature into oligodendrocytes and was increased in myelinating oligodendrocytes (Figure 3A). This is perhaps consistent with elevated KCNMB4 expression in chronic inactive multiple sclerosis lesions\textsuperscript{117}. In contrast mouse OPC and oligodendrocytes do not seem to express much Kcnmb2 (Figure 3B, 3C). However, as occurs in humans, Kcnma1 is most marked in the OPC and is down-regulated as oligodendrocytes mature and myelinate (Figure 3C). Likewise, Kcnmb4 can sometimes be found at higher levels in OPCs, but persists in mature oligodendrocytes to be the dominant BK channel isoform (Figure 3B, 3C). Kcnmb4 is expressed on the cell membrane and is also expressed in mitochondria\textsuperscript{21}. Loss of Kcnma1 message during development is consistent with protein expression and functional calcium-induced signalling activity\textsuperscript{118} and may play a role in oligodendrocyte differentiation. Additionally, electrophysiological recordings of increased oligodendrocytes depolarisation corresponded to the increased intracellular fluorescence from labelled Ca\textsuperscript{2+} upon glutamate-induced stimulation; which occurred only when the BK channel blocker iberiotoxin was added\textsuperscript{118}. This suggests a role of BK channels to regulate Ca\textsuperscript{2+} influx to protect oligodendrocytes from excitotoxic stress. Other evidence indirectly supports this. As such the fundamental subunits of the NMDARs, NR1, NR2 and NR3 co-localise with myelin protein from primary optic nerve oligodendrocytes upon immunohistochemical staining\textsuperscript{22}. Blocking NMDARs substantially blocked myelin damage upon chemically induced ischaemia in vitro\textsuperscript{23}. This was the first evidence of axo-myelinic signalling, indicating that glutamate released from the axon can cause Ca\textsuperscript{2+} to enter oligodendrocytes through the myelin sheath. Importantly, it has been found that mature oligodendrocytes express NMDARs, and that small quantities of excitatory neurotransmitters diffusing between axon and myelin could form sufficiently high concentrations to give rise to large Ca\textsuperscript{2+} transients within mature oligodendrocytes\textsuperscript{22}. In health, oligodendrocytes already communicate with axons through NMDAR for trophic support\textsuperscript{24} and BK channels form complexes with this receptor\textsuperscript{25}. Therefore, when activated, BK channels could protect oligodendrocytes from axon-induced excitotoxicity by increasing hyperpolarisation. Prolonging APs may increase the duration of the desensitised state of ionotropic channels and VGCCs to limit Ca\textsuperscript{2+} influx. In demyelinating pathology, the excessive excitotoxicity could inhibit the endogenous protection by BK channels to oligodendrocytes. The addition of an activator could re-open these, re-establishing protective effects. A counter argument is that high extracellular potassium is primarily responsible by increasing length of neuronal depolarised state. Damaged oligodendrocytes may have a dysfunctional inward rectifier potassium channel, so K\textsuperscript{+} clearance is faulty\textsuperscript{126}. Large levels of excitatory stimulation of myelin may result because when neurons are demyelinated or damaged they upregulate sodium channels, and subunits which maintain the depolarised state\textsuperscript{65}. In this scenario, BK channel activators might be counter-productive by increasing extracellular K\textsuperscript{+}; but possibly only if K\textsuperscript{+} clearance is faulty.

BK channel activators could be used therapeutically to preserve function in demyelinating diseases, particularly MS. As described above, currently the standard treatment for MS targets inflammation, but curbing the pathological attack by the immune system does not protect from demyelination or excitotoxicity. Therefore, it does not prevent neurodegeneration or restore functionality lost\textsuperscript{111}. In MS, BK channels are expressed in both myelin and the axons it covers. Crucially, in chronically injured white matter, their activation upon Ca\textsuperscript{2+} influx was observed only upon axon exposure subsequent to chronic spinal cord injury\textsuperscript{126}. Addition of the BK channel activator isopimaric acid preserved myelination after spinal cord injury in rats\textsuperscript{95}, where functionality correlated with preserved myelinated tracts. This suggests that a BK channel
Figure 3. Oligodendrocyte expression of BKCa channels in humans and mice. The expression of BK channels; platelet-derived growth factor receptor alpha (PDGFRα) and chondroitin sulphate proteoglycan four (CSPG4/NG2) as markers for oligodendrocyte precursor cells (OPC) and committed oligodendrocyte precursors (COP); myelin oligodendrocyte glycoprotein (MOG) and proteolipid protein one (PLP1) as markers of mature oligodendrocytes (OL); human glutamatergic neurons (Neuro2 GAD2 0.02, SLC17A7 2.11 (Jäkel et al. 2019); and aquaporin 4 (AQP4) and glial fibrillary acidic protein (GFAP) as markers for astrocytes channels was extracted from public data bases (A) Expression of BK channels in human cells in human white matter tissues extracted from the oligointernode (https://ki.se/en/mbb/oligointernode) (B) Expression of human and mouse BK channels from cortical brain tissue using 10X single cell RNAseq from the Allen Brain Atlas (www.portal.brain-map.org) (C) BK expression in OPC and mature oligodendrocytes from RNAseq data from the Oligointernode portal and the Brain RNA-Seq portal (www.brainrnaseq.org). Data is expressed as fragments per kilobase of transcript per million mapped reads (FPKM). * = data values reduced 10 times ** = data values reduced 100 times.
activator could target demyelination to preserve functionality in MS.

Only a few BK channel activators have been studied in the clinic, BMS-204352 (Maxipost) was developed for stroke while andolast is reported to be in phase III for asthma. Unoprostone isopropyl is an atypical prostanoid used topically in the treatment of glaucoma. VSN16R was recently trialled in people with MS for muscle spasticity. This trial focussed on spasticity endpoints up to a week after administration of the drug and no remyelination parameters were studied.

**Conclusion**

There are numerous ways excessive glutamate may cause oligodendrocytes toxicity in demyelinating pathology. Neuroinflammation increases neuronal signalling which will damage neurons, that will release even more glutamate. The vicious cycle of damage by oxidative stress to cellular metabolism will exacerbate pathology. Close proximity to neurons, glutamatergic receptor expression and high vulnerability to oxidative stress makes oligodendrocytes particularly susceptible to excitotoxicity compared to other lesion tissue. Oligodendrocytes perivascular location, as part of white matter, further increases this susceptibility, especially in MS where neuroinflammatory oxidative stress is central to demyelination.

BK channels can modulate cellular excitability and are even proposed to protect cells from release of excessive levels of excitatory neurotransmitters, by pairing with ionotropic glutamate receptors and VGCCs. It is plausible that BK channels could protect oligodendrocytes from excitotoxicity, supported by their expression in these cells. With high levels of glutamate BK channels become inactivated, possibly explaining their inability to protect cells in models of demyelination. It is therefore feasible that BK channel activators might protect pathological oligodendrocytes from excitotoxic stress. Considering oligodendrocytes primary function is axon myelination, then if BK channels preserve oligodendrocytes integrity myelination would also be preserved.

There is still little evidence of the functions of BK channels on oligodendrocytes and the involvement of BK channels in MS is an angle of research that has yet to be explored extensively. Therefore, in vitro tests are fundamental to establish a first functional link between BK channels, oligodendrocytes, oxidative stress and myelin production, to verify the importance of conducting these investigations and possibly prompt more. Crucially, it is important to determine whether BK channels are expressed by oligodendrocytes, whether this expression depends on developmental stage, but also effects of glutamate-induced excitotoxicity in the context of myelination and the ability to target BK channels in vivo. This would define whether increasing the open conformation of BK channels with activating agents is a promising neuroprotective therapy to be used in parallel to immunosuppressive agents for the treatment of MS.

**Abbreviations**

ADCC: antibody-dependent cellular cytotoxicity

AMPAR: alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor

AP: action potential

APC: antigen presenting cell

ATP: adenosine triphosphate

BBB: blood brain barrier

BK: big conductance Ca\(^{2+}\) activated K\(^{+}\) (channel)

CD: cluster of differentiation

CNP: 2',3'-cyclic nucleotide 3'-phosphodiesterase

CNS: central nervous system

CSF: cerebrospinal fluid

Cx: connexin

DMEM: modified minimal essential medium

DMT: disease modifying therapy

DNA: deoxyribonucleic acid

EAE: experimental autoimmune encephalomyelitis

ERK: extracellular-signal regulated kinase

FBS: foetal bovine serum

GABA: gamma-aminobutyric acid

GAPDH: glyceraldehyde 3-phosphate dehydrogenase

GFAP: glial fibrillary acidic protein

GLUT1: glucose transporter 1

GM-CSF: granulocyte- macrophage colony stimulating factor

IFN\(\gamma\): interferon gamma

IgG: immunoglobulin G

IL: interleukin

KCNM: Ca\(^{2+}\)-activated K\(^{+}\) channel subunit

Kir: inward rectifying K\(^{+}\) channel

KO: knockout

Kv1: voltage gated K\(^{+}\) channel

MAG: myelin-associated glycoprotein

MAPK: mitogen-activated protein kinase
MBP: myelin basic protein  
MCT: monocarboxylate transporter  
MDA: malondialdehyde  
MOG: myelin oligodendrocyte glycoprotein  
MRI: magnetic resonance imaging  
MS: multiple sclerosis  
Nav1: voltage gated Na+ channel  
NFkB: nuclear factor kappa-light-chain-enhancer of activated B cells  
NMDA(R): N-methyl-D-aspartate (receptor)  
OPC: oligodendrocyte progenitor cell  
PBS: phosphate-buffered saline  
qPCR: quantitative polymerase chain reaction  
RNS: reactive nitrogen species  
ROS: reactive oxygen species  
RRMS: relapsing-remitting multiple sclerosis  
SPMS: secondary progressive multiple sclerosis  
STREX: stress-axis regulated exon  
TBARs: thiobarbituric acid reactive substance assay  
Th: T helper (cell)  
TNFα: tumour necrosis factor alpha  
TNFβ: tumour necrosis factor beta  
TRP: transient receptor potential (channel)  
VGCC: voltage gated Ca2+ channel  
4-AP: 4-aminopyrimidine

Department of Neuroscience, University of Minnesota, Minneapolis, MN, USA

This review summarizes the current literature on the role of excitotoxic stress, myelination, and BK channels in MS pathology. The topic is timely and important. The manuscript is well written. However, there are a couple of concerns:

1. The authors stated that "preserving myelin might provide a better neuroprotective strategy than remyelination". In fact, this manuscript concentrates on demyelination, rather than remyelination. It could be better to replace remyelination with demyelination in the title.

2. This manuscript concentrates on demyelination, particularly in MS. It is important to summarize the current literature on mechanisms governing mature oligodendrocyte viability in MS and its animal models. Recent studies demonstrate the critical roles of PERK, NF-κB, among other signaling pathways in modulating oligodendrocyte viability and demyelination in MS and its animal models. These studies should be cited and discussed.

Is the topic of the review discussed comprehensively in the context of the current literature?
Yes

Are all factual statements correct and adequately supported by citations?
Yes

Is the review written in accessible language?
Yes

Are the conclusions drawn appropriate in the context of the current research literature?
Yes

Competing Interests: No competing interests were disclosed.
Reviewer Expertise: oligodendrocyte biology and pathology

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Reviewer Report 26 August 2021

Is the topic of the review discussed comprehensively in the context of the current literature?

In the review by Rupnik et al., the role of excitotoxicity in oligodendrocytes was approached through a physiological, clinical, and biophysical perspective, which allows the reader to understand the basics on the origin, progression, and possible therapies for diseases associated with demyelination.

Are all factual statements correct and adequately supported by citations?

In the manuscript by Rupnik et al., the statements were adequately supported by citations which included some classic works (Hursh, 1939; Waxman et al., 1977; Waxman et al., 1984) and articles published in the last ten years.

Is the review written in accessible language?

The review was written fluently, clearly and the topics were discussed deeply enough. The structure of the paper was clearly defined at the beginning of the text (page 3).

Are the conclusions drawn appropriate in the context of the current research literature?

The authors summarized the causes and effects of oligodendrocytes toxicity and proposed an alternative therapy to treat pathologies associated with demyelination. One strategy involves modulation of the large conductance, Ca\textsuperscript{2+} and voltage-activated BKCa channel, which activation might prevent Ca\textsuperscript{2+} overload to protect oligodendrocytes from excitotoxic stress. Of note, a
similar mechanism has been observed in cardiac mitochondria in rodents, where the BKCa channel expresses and its activation reduces the driving force for Ca\(^{2+}\), preventing overload and cell death (Singh et al., 2013; Balderas et al., 2019). Moreover, as observed in cardiac mitochondria, the functional association of mitoBK\(_{\text{Ca}}\) with regulatory subunits \(\beta 1\) broadens the spectrum of molecular targets suitable for the development of new and more directed therapies. Targeting the pore forming BKCa channel \(\alpha\)-subunit with current and novel drugs needs to overcome the broad localization of the channel in brain cells. Considering that BKCa is expressed ubiquitously in brain cells it is essential to establish the differential and perhaps localized expression of BKCa channels and/or its regulatory subunits (\(\beta 1\)-4; \(\gamma 1\)-4) in oligodendrocytes. This would allow designing a more specific therapy alternative to immunosuppressive agents.

In summary, the review presented by Rupnik and coworkers represents a good collection of most recent information in the field of oligodendrocytes and the pathologies associated with demyelination, highlighting a possible role of the BKCa channel in preventing Ca\(^{2+}\) overload and reducing excitotoxic stress. Our main suggestion would be to include a comment on the importance of the expression and association with BKCa-regulatory subunits and their possible use as novel targets for future therapies.

The benefits of publishing with F1000Research:

- Your article is published within days, with no editorial bias
- You can publish traditional articles, null/negative results, case reports, data notes and more
- The peer review process is transparent and collaborative
- Your article is indexed in PubMed after passing peer review
- Dedicated customer support at every stage

For pre-submission enquiries, contact research@f1000.com
