Abstract
Hemoglobins (Hbs) corresponding to non-symbiotic (nsHb) and truncated (tHb) Hbs have been identified in rice (Oryza). This review discusses the major findings from the current studies on rice Hbs. At the molecular level, a family of the nshb genes, consisting of hb1, hb2, hb3, hb4 and hb5, and a single copy of the thb gene exist in Oryza sativa var. indica and O. sativa var. japonica. Hb transcripts coexist in rice organs and Hb polypeptides exist in rice embryonic and vegetative organs and in the cytoplasm of differentiating cells. At the structural level, the crystal structure of rice Hb1 has been elucidated, and the structures of the other rice Hbs have been modeled. Kinetic analysis indicated that rice Hb1 and 2, and possibly rice Hb3 and 4, exhibit an extremely high affinity for O₂, whereas rice Hb5 and tHb possibly exhibit a low to moderate affinity for O₂. Based on the accumulated information on the properties of rice Hbs and data from the analysis of other plant and non-plant Hbs, it is likely that Hbs play a variety of roles in rice organs, including O₂-transport, O₂-sensing, NO-scavenging and redox-signaling. From an evolutionary perspective, an outline for the evolution of rice Hbs is available. Rice nshb and thb genes vertically evolved through different lineages, rice nsHbs evolved into clade I and clade II lineages and rice nshbs and thbs evolved under the effect of neutral selection. This review also reveals lacunae in our ability to completely understand rice Hbs. Primary lacunae are the absence of experimental information about the precise functions of rice Hbs, the properties of modeled rice Hbs and the cis-elements and trans-acting factors that regulate the expression of rice hb genes, and the partial understanding of the evolution of rice Hbs.

Abstract

Plant hemoglobins (Hbs) are a group of proteins found in plants, responsible for the transport of oxygen and nitrogen. They are unique to plants and are distinct from their animal counterparts, making them an important area of research.

Introduction

Two decades ago Taylor and co-workers reported the cloning and sequencing of a hemoglobin (Hb) cDNA from barley. This was the first report about the existence of Hbs in monocotyledonous plants. Since then, Hbs have been identified in a number of monocots, including rice, maize, and wheat. Rice Hbs and genes coding for these proteins are well-characterized, thus in many aspects rice Hbs are a model to understand monocot and land plant Hbs.

Generalities on hemoglobins

Hb is known to the reader because this protein is responsible for the red color of vertebrates’ blood. However, Hbs are widely distributed in living organisms, ranging from bacteria to mammals. The tertiary structure of Hbs consists of a specific arrangement of six to eight α-helices, designated as A to H, which are globinfold. This protein folding forms a hydrophobic pocket where a Fe-heme prosthetic group is located.

Land plant hemoglobins

Land plant Hbs were first identified by Kubo in soybean root nodules. Few years after Kubo’s discovery, these proteins were named as leghemoglobins (Lbs) by Virtanen and Lane because they were only found in the symbiotic (N₂-fixing-) nodules of the leguminous plants. Lbs are the most abundant soluble proteins in nodules (e.g. in soybean nodules their concentration is as high as 3 mM). The x-ray analysis of lupin Lb revealed that the tertiary structure of Lbs was remarkably similar to that of the sperm whale myoglobin. This evidence demonstrated that Lbs are plant Hbs and indicated that plant and animal Hbs evolved from a common ancestor more than 600 mya. Subsequent work led to the identification of Lb-like (or symbiotic) Hbs in nodules of actinorhizal plants, purification of an Hb from the root nodules of the dicotyledonous non-legume Parasponia andersonii, cloning and sequencing of an hb gene from the non-nodulating dicot Trema tomentosa, and detection of Hbs in non-symbiotic organs from several land plants, including primative bryophytes and evolved angiosperms. Until now three types of Hbs have been identified in land plants: the symbiotic Hbs, which include Lbs that are specifically located within nodules of the N₂-fixing land plants, and the non-symbiotic Hbs that are located within non-symbiotic and symbiotic organs of primitive and evolved land plants. Based on sequence similarity the Hbs are further classified into type 1 and type 2 Hbs.

Distribution of hemoglobins in monocotyledonous plants

Monocots are a large family of flowering plants that includes cereals. Cereals, such as rice, maize, and wheat, are the main source of food for humans. Because of this, during that last decade the genomes of a number of cereals have been sequenced. This allowed the identification of novel cereal Hbs. The search of hb genes in databases by G. Rodríguez-Alonso and R. Arredondo-Peter revealed that Hbs sequenced in the Brachypodium distachyon, Hordeum vulgare (barley), Oryza glaberrima (rice), O. rufipogon, O. sativa (rice) var. indica, O. sativa (rice) var. japonica, Panicum virgatum (switchgrass), Setaria italica (foxtail millet), Sorghum bicolor (sorghum), Triticum aestivum (wheat) and Zea mays ssp. mays (maize) genomes. The highest number of Hbs (5) exists in O. sativa var. indica and O. sativa var. japonica. Whereas one to three Hbs exist in barley, Brachypodium, foxtail millet, rice, O. glaberrima, O. rufipogon, sorghum, switchgrass and wheat. Also, with the exception of wheat, which contains two copies of the tbh gene, a single copy of tbh was identified in the genome of Brachypodium, barley, O. sativa var. indica, O. sativa var. japonica, switchgrass, foxtail millet, sorghum and maize. Little is known about Hbs from non-cultivated monocots. The only Hb reported from a non-cultivated monocot is that of teosinte (Z. mays ssp. parviglumis), which is postulated as the ancestor of maize. Analysis by Southern blot using the teosinte hb gene as probe showed that apparently a single copy of hb exists in teosinte (J. Sáenz-Rivera and R. Arredondo-Peter, unpublished results). Sequence comparison revealed that maize and teosinte Hb polypeptides are identical.

Early search and identification of rice hemoglobins

Monocots were a target for searching Hbs after these proteins were detected in non-symbiotic organs of dicotyledonous plants (see subsection above). At that time, monocot genomes had not...
been sequenced. Searching approaches consisted in detecting Hb polypeptides and hh genes by spectroscopy and molecular biology methods, respectively. Attempts to detect absorption maxima in the Soret (~410 nm) and Q (~500 to 550 nm) regions, which are characteristic of ferric (Fe$^{3+}$), ferrous (Fe$^{2+}$) and liganded Hbs, were unsuccessful (R. V. Klucas and C. A. Appleby, unpublished results) mostly due to the very low Hb concentration (~50 to 100 nM) in plant non-symbiotic organs.$^{5,6}$ At the molecular level a consensus probe designed from legume and non-legume (T. tomentosa, P. andersonii and Casuarina glauca) Hb sequences$^{71}$ hybridized with hh-like sequences from rice and other monocot total DNAs (Figure 1). This observation suggested that hh sequences exist in monocots, however hybridizing fragments were not subsequently cloned and sequenced in order to verify if they actually corresponded to hh genes.

Rice Expressed Sequence Tags (ESTs) were first deposited in databases early in the 1990’s. The first rice Hb (Hb1 and Hb2) sequences were detected from ESTs deposited in the DNA Data Bank of Japan (DDBJ) database.$^{72}$ Rice Hb1 and Hb2 corresponded to clones C741 and C2576 with DDBJ accession number D15507 and D38931, respectively. Rice hh1 and hh2 genes were subsequently amplified by PCR, cloned and sequenced. Sequence analysis revealed that rice hh1 codes for non-symbiotic Hb1 and that rice hh2 codes for non-symbiotic Hb2.$^{7}$ Afterwards, sequencing of the rice (O. sativa L. ssp. indica) genome more than a decade ago$^{8}$ allowed the identification of a family of rice nshb genes and a single copy of the rice thb gene (see subsection below).

Molecular biology of rice hemoglobins

Rice hemoglobin genes

The O. sativa var. indica and O. sativa var. japonica genomes are fully sequenced, and the O. glaberrima and O. rufipogon genomes are partially sequenced. Rice genome sequences are mainly available from the GenBank (www.ncbi.nlm.nih.gov) and Phytozome (http://www.phytozome.org/) databases. Search of Hb sequences in the above databases showed that a family of the nshb genes, consisting of hh1, hh2, hh3, hh4 and hh5, and a single copy of the thb gene exist in the O. sativa var. indica and O. sativa var. japonica genomes. A single copy of the nshb gene was detected in the O. glaberrima and O. rufipogon genomes, however hhb genes have not yet been detected in these plants.$^{61}$ Given that the sequencing of the O. glaberrima and O. rufipogon genomes is in progress the identification of hh genes in these genomes is incomplete. Thus, the following discussion will focus on the O. sativa var. indica and O. sativa var. japonica hbs.

The structure of known rice hh genes corresponds to four exons and three introns, with introns located at similar position as all of the known plant hh genes.$^{7}$ Canonical TATA boxes and a variety of potential promoters exist upstream of the rice hh genes which suggests that rice hbs are functional and that the regulation of the hh genes in this plant is complex.$^{6-7}$ Figure 2 shows the localization of hbs in the O. sativa chromosomes and mapping of hbs in the O. sativa genome. Rice hh1, hh3 and hh4 cluster forming the hh1-hh4 cluster$^{7}$ which is localized in chromosome 3. Rice hh2 is also

![Figure 1](https://example.com/figure1.png)

Figure 1. Early (1991) detection of rice, maize, sorghum and wheat hh-like sequences by dot-blot hybridization (R. Arrendondo-Peter, unpublished results). Approximately 20 μg of undigested total DNA was used as template and a consensus oligonucleotide for legume and non-legume plant Hbs$^{77}$ was used as probe. Sequence of the consensus probe was 5'-GTA GCC TAT GAT GAA TTG GCA GCT GCA-3'. The probe was labeled by nick translation with Biotin-dATP using a Bionick labeling system (Gibco BRL). The membrane was prehybridized with SSC 2× for 4h at 42°C, hybridized overnight at the same temperature, washed at high stringency (SSC 2×/SDS 0.1% for 3 min at room temperature, SSC 0.2×/SDS 0.1% for 15 min at room temperature and SSC 0.16×/SDS 0.1% for 15 min at 65°C) and incubated with the streptavidin-alkaline phosphatase conjugate and the BCIP/NBT mix to develop color. Animal (salmon sperm and calf thymus) and legume DNAs were included as negative and positive controls, respectively.
Figure 2. Localization of hbs in the *O. sativa* chromosomes (A) and mapping of hb genes into the *O. sativa* genome (B). The hb genes were localized in the rice chromosomes by BlastN analysis using the Rice (*O. sativa*) genome resource from the GenBank database as template and the sequence for the rice *hb1*, 3 and 4 (GenBank accession number AF335504), *hb2* and 5 (GenBank accession numbers AF335503 and EF061459, respectively) and *thb* (GenBank accession number NM_001064507) genes as probes. The *hb* (black boxes) and flanking (gray boxes) genes were mapped into 50 kb fragments of the *O. sativa* genome by BlastN2.2.26+ analysis using the Phytozome V9.1 server (www.phytozome.org) and the above *hb* sequences as probes. Arrows indicate the transcription orientation. Information for each gene corresponds to predicted protein (following the Phytozome nomenclature), locus name in the *O. sativa* genome and position at the *O. sativa* chromosome. Gene sizes and distance between genes are not shown at scale. Pltd, chloroplast chromosome; MT, mitochondrial chromosome.
localized in chromosome 3 but 467 kb upstream of the \textit{hb1-hb4} cluster. In contrast, rice \textit{hb5} and \textit{ihb} genes are localized in chromosomes 5 and 6, respectively (Figure 2A). Rice \textit{hbs} are flanked by a variety of genes with known and unidentified functions (Figure 2B). However, with the exception of genes coding for a ternary complex factor macrophage inflammatory protein MIP1 and an ubiquitin fusion protein which are located 239 and 411 nucleotides up- and downstream of the \textit{hb1-hb4} cluster, respectively, distance of flanking genes to \textit{hbs} is >1 kb. This suggests that co-expression of \textit{hb} and flanking genes is unlikely.

**Gene expression and localization of hemoglobins in rice organs**

The expression of \textit{hb} genes and localization of Hb polypeptides have been analyzed in rice growing under normal and stressed conditions. Under normal conditions the expression level of rice \textit{nshb} was low \cite{2,25,78}. However, analysis by RT-PCR revealed that \textit{hb1}, \textit{hb2} and \textit{hb5} genes were expressed in embryonic and vegetative organs obtained from rice plants grown under a normal environment \cite{25,78}. Specifically, transcripts for rice \textit{Hb1} were detected in embryos, seminal roots, leaves and roots, transcripts for rice \textit{Hb2} were detected in embryos, coleoptiles, seminal roots and leaves, and transcripts for rice \textit{Hb5} were detected in embryos, coleoptiles, seminal roots, leaves and roots. Likewise, evaluation of the \textit{β}-glucuronidase (GUS) activity from a construct containing the rice \textit{nshb2} gene promoter that is responsive to the cytokinin-regulated \textit{ARR1} trans-acting factor showed that this promoter is activated in roots, the vasculature of young leaves, flowers and the pedicel/stem junction of transgenic \textit{Arabidopsis} \cite{52}. In addition, a variety of potential promoters was identified upstream of the rice \textit{nshb} genes, such as those involved in the ethylene synthesis, photoregulation, heat shock response and plant defense signaling \cite{70,75,77}. However the activities of these promoters have not been determined.

Transcriptomic analyses revealed that \textit{nsHb} and \textit{tHb} transcripts coexist in rice embryonic and vegetative organs (Table 1). This evidence suggests that \textit{nsHb} (\textit{i.e.} \textit{Hb1}, \textit{Hb2}, \textit{Hb3}, \textit{Hb4} and \textit{Hb5}) and \textit{tHb} polypeptides coexist and probably function in rice organs. Immunoanalysis by Western blot and confocal microscopy using a polyclonal anti-rice \textit{Hb1} antibody revealed that Hb polypeptides exist in rice seeds and in rice leaves and roots from 2 to 14 weeks after seed germination. These analyses also revealed that Hb polypeptides exist in the cytoplasm of differentiating cells of the root cap, schlerenchyma, aleurone, and in the vasculature, principally in the differentiating xylem \cite{20,79,78}. However, the anti-rice \textit{Hb1} antibodies cross-react with different rice Hbs (G. Sarath and E. J. H. Ross, unpublished results) and thus it is not known which Hb polypeptides were detected in the above analyses by the anti-rice \textit{Hb1} antibodies.

It is well documented that land plant \textit{hb} genes are either up- or down-regulated by stress conditions \cite{13,23,24,70}. Table 1 shows that Hb transcripts coexist in rice growing under cold, drought and salt stress conditions. Also, Ohwaki and co-workers \cite{75} reported that \textit{nshb1} and \textit{nshb2} are induced by nitrate, nitrite and NO in cultured rice cells. These observations indicate that rice \textit{hbs} gene response to a variety of stress conditions. However, the detection of Hb polypeptides by Western blot using the anti-rice \textit{Hb1} antibodies showed that level of Hbs increased in rice etiolated leaves and flooded roots, but not in rice plants subjected to oxidative (H$_2$O$_2$), nitrosative (SNP) and hormonal (2,4-D) stresses. These observations suggest that rice Hbs do not appear to be part of a generalized stress response, but may be functional in plant organs subjected to specific stress conditions \cite{79}.

### Table 1. Detection of Hb transcripts in organs from rice growing under normal and (cold, drought and salt) stressed conditions.

Rice Hb transcripts were detected in plant organs using The Rice Genome Annotation Project database (http://rice.plantbiology.msu.edu) and hemoglobin as keyword (S. Castro-Bustos and R. Arredondo-Peter, unpublished).

**Structure and biophysical properties of rice hemoglobins**

### Structure of rice hemoglobins

Rice \textit{hb} genes are functional and code for Hb polypeptides with a predicted molecular mass of ~16 to 19 kDa \cite{23,76,77,79}. Rice \textit{Hb1} was the first monocot \textit{nsHb} whose crystal structure was elucidated \cite{84}. This protein crystalizes as a dimer, thus it is possible that \textit{in vivo} rice \textit{Hb1} forms dimers when its concentration is ≥1 mM \cite{85}. After the elucidation of the rice \textit{Hb1} structure the tertiary structure of rice \textit{Hb2} \cite{23,76,79}, \textit{Hb3}, \textit{Hb4} and \textit{Hb5} \cite{53} (CASPUR PMDB ID PM0075009, PM0075873, PM0076005 and PM0075011, respectively) was predicted using computational methods and rice \textit{Hb1} (PDB ID 1D8U) as the structural homolog. The crystal structure of rice \textit{Hb1} and that of predicted rice \textit{Hb2}, \textit{Hb3} and \textit{Hb4} is highly similar. The tertiary structure of these proteins consists of six helices that fold into the 3/3-folding (see subsection on Generalities on hemoglobins). However, the
structure of rice Hb1 to 4 is characterized by the existence of a short pre-helix A located at the N-terminal and an extended and poorly ordered CD-loop. The heme pocket in these proteins differs from that in “traditional” Hbs because the proximal and distal His side chains coordinate the Fe-heme forming a hemichrome (Figure 3), resulting in that Fe-heme from rice Hb1 to 4 is hexacoordinate. Also, the amino acid residues (V50, S53, E123, V124, F127 and A128) located at the monomer-monomer interface of dimeric rice Hb1 are highly conserved in rice Hb2 to 4. This suggests that rice Hb1 to 4 can potentially form homo- or hetero-dimers if the hb1 to 4 genes coexpress in rice organs. The tertiary structure of rice Hb5 also consists of six helices that fold into the 3/3-folding. However, rice Hb5 differs from rice Hb1 to 4 in missing 11 amino acids in helix E which results in that the length of the CD-loop and helix E in the predicted Hb5 structure are unusually long and short, respectively. An apparent consequence from this characteristic is that distal His is located far away (13.92 Å, compared to 2.11 Å in rice Hb1) from the Fe-heme within the predicted Hb5 structure, resulting in that Fe-heme from rice Hb5 could be pentacoordinate. The amino acid residues located at the monomer-monomer interface of dimeric rice Hb1 are poorly conserved in rice Hb5 which suggests that rice Hb5 exists in vivo as a monomer.

The folding pathway and kinetics of rice nsHbs were predicted using the Average Distance Map (ADM) method. This analysis indicated that rice Hb1 and Hb2 could fold in the C → N direction at a moderate rate, that rice Hb3 could fold in the N → C direction at a fast rate, and that rice Hb4 and Hb5 could fold in the N → C direction at a moderate rate. Thus, it appears that the predicted folding pathway and kinetics among rice nsHbs are diverse. Also, the ADM analysis showed that pre-helix A and CD-loop apparently do not play a role during the folding of rice nsHbs. The ADM analysis has not been performed on rice tHb, thus the predicted folding pathway and kinetics for this protein are not known.

Rice (O. sativa) tHb (GenBank accession number NP_001057972) is 172 amino acids in length, which corresponds to a globin domain (position 26 to 147) flanked by N- and C-terminal extensions. No monocot Hb has been analyzed by x-ray crystallography, however the tertiary structure of a rice tHb was predicted using computational methods (Figure 3). The predicted structure of rice tHb is highly similar to the crystal structure of an Arabidopsis thaliana tHb. The globin domain from rice and A. thaliana tHbs folds into the 2/2-folding (see subsection on Generalities on hemoglobins). Similarly to the A. thaliana tHb structure, flanking regions to the globin domain of predicted rice tHb correspond to an N-terminal helical extension and a C-terminal unfolded extension (Figure 3). The high similarity between the crystal structure of A. thaliana tHb and the predicted structure of rice tHb suggests that the biochemical properties and function of dicot and monocot tHbs are similar.

Spectroscopic characteristics of rice hemoglobins

Visible spectroscopy (see subsection Early search and identification of rice hemoglobins) is a tool to analyze the redox state of and ligand-binding to the Fe-heme of Hbs. Rice Hb1 is the only rice nsHb that has been spectroscopically characterized. This protein exhibits spectral characteristics that are similar to other Hbs. However, rice Hb1 exhibits distinctive absorption maxima in the deoxyferrous form: the unligated ferrous state exhibits maxima at 526 and 556 nm which are characteristic of hexacoordinate

**Figure 3.** Crystal structure of rice Hb1 (PDB ID 1DBU) and predicted structure of rice tHb. The tertiary structure of rice tHb was modeled using the automated mode of the I-Tasser server (http://zhanglab.ccmb.med.umich.edu/I-TASSER) and the crystal structure of the Thermobifida fusca Hb (PDB ID 2BMM) as the structural homologue. Model for the rice tHb is deposited in the Caspur Protein Model Database (http://bioinformatics.cineca.it/PMDB/main.php) under the ID number PM0079484. Helices are indicated with letters A to H. Note the overlapping of helices A, E and F to helices B, G and H in (3/3-folding) rice Hb1, and overlapping of helices B and E to helices G and H in (2/2-folding) rice tHb. Heme prosthetic group is shown in dark green color and proximal and distal His are shown in light brown color.
Fe-heme \(94\). This is in contrast to pentacoordinate Hbs which display a broad peak centered at 556 nm in their deoxyferrous form \(95,96\). The distal ligand that coordinates the Fe-heme in rice Hb1 was identified as His74 by site directed mutagenesis. Absorbance spectra of the ferric and deoxyferrous forms of an H74L mutant of rice Hb1 showed no evidence of His coordination. Also, the addition of exogenous imidazole to ferric and deoxyferrous H74L mutant resulted in a spectrum identical to that of the wild-type rice Hb1. This evidence indicated that in rice Hb1 the distal ligand to Fe-heme is His74. A similar case can be predicted for rice Hb2 to 4. In contrast, distal His appears to be located far away from the Fe-heme in the predicted structure of deoxyferrous rice Hb5, resulting in that Fe-heme in rice Hb5 could be pentacoordinate \(75\).

Rice tHb has not been subjected to spectral analysis, however the predicted structure of this protein (Figure 3) is highly similar to the crystal structure of an A. thaliana tHb \(97\) (see subsection on Structure of rice hemoglobins). The absorption spectra of an A. thaliana tHb showed that Fe-heme from this protein is pentacoordinate \(92,93\). Thus, it is likely that Fe-heme in rice tHb is pentacoordinate and that the \(O_2\)-binding properties of rice tHb are similar to those of pentacoordinate Hbs, i.e. the \(O_2\)-association and -dissociation rate constants are high.

**Kinetic properties of rice hemoglobins**

Analysis of ligand-association and -dissociation rate constants of penta- and hexacoordinate Hbs using stopped-flow methods indicated that these proteins exhibit low to moderate and high affinity for \(O_2\), respectively. Rice Hb1 to 4 are hexacoordinate and apparently rice Hb5 and tHb are pentacoordinate. The \(O_2\)-association rate constants for hexacoordinate rice Hb1 and 2, and possibly for rice Hb3 and 4, are similar to those of other \(O_2\)-transport and -storage proteins, such as the spermwhale myoglobin and soybean LbBs \(98,99\). However, in rice Hb1 \(1\) and \(2\), and possibly in rice Hb3 and 4, the bound \(O_2\) is stabilized by distal His after binding to the Fe-heme, which results in very low \(O_2\)-dissociation rate constants. The \(O_2\)-association and -dissociation rate constants of hexacoordinate rice Hb1 and 2, and possibly of rice Hb3 and 4, result in that the affinity of these proteins for \(O_2\) is extremely high (e.g. \(K_{O_2} = 1,800\) and \(1,316\) \(\mu\)M\(^{-1}\) for rice Hb1 and 2, respectively \(9,16\)). In contrast, the \(O_2\)-association and -dissociation rate constants of pentacoordinate rice Hb5 and tHb could be moderate to high, which could result in a low to moderate affinity for \(O_2\).

**Postulated migration routes for gaseous ligands to the Fe-heme in rice Hb1**

The bis-histidyl hexacoordinated form of rice Hb1 displays a hydrophobic distal cavity which appears to be connected with the external solvent through the position of Phe44 (also known as FB10 because it occupies the tenth position in helix B). It was suggested that this amino acid regulates the migration of small ligands in rice Hb1, for example in ligand binding to the Fe-heme, ligand migration through internal docking sites and ligand release into the external solvent \(9,10\). Kinetic analysis after laser flash photolysis of rice Hb1 encapsulated in silica gel combined with computational analysis revealed the existence of two channels in the rice Hb1 CO-bound species. The first channel is located in the distal region of the heme pocket and is connected with a secondary channel that is directly connected with the external solvent. Apparently, the position of FB10 in hexacoordinated rice Hb1 leaves the distal heme pocket accessible to the external solvent, however after the ligand entrance the phenyl ring rotates closing the cavity and thus hindering the exit of the bound ligand \(100\). Thus, together with distal (H74) His (see subsection Spectroscopic characteristics of rice hemoglobins) and aromatic (F40, F41, F55, F57, Y145 and L126) amino acids that are located in the distal region of the heme pocket, FB10 appears to regulate hexacoordination and functioning of rice Hb1.

**Postulated functions for rice hemoglobins**

While data on the localization, kinetics, regulation and structure of rice Hbs have accumulated, little work has been performed to fully understand the function of these proteins in rice organs. However, previous work from other plant and non-plant Hbs provides data that enable us to propose potential functions for rice Hbs. Rice Hbs could potentially function within cells through \(O_2\)-transport and -signaling, binding to small molecules (most notably NO) and other as yet undetermined mechanisms. Here we evaluate the evidence for and against these modes of action.

Oxygen transport is a major function of many Hbs. This process requires that the kinetics of \(O_2\)-binding do not limit the \(O_2\)-diffusion process \(90,91\). Based on the concentration of Hb polypeptides in rice organs (~50 to 100 nM) \(91\), the \(O_2\)-association rate constant of rice Hb1 and 2 (68 and 50 \(\mu\)M\(^{-1}\) s\(^{-1}\)) and possibly that of rice Hb3 to 5 and tHb (see subsection Kinetic properties of rice hemoglobins), and the free \(O_2\) concentration in aerated rice roots (<1.4 \(\mu\)M) \(92\), it is likely that Hbs would be substantially oxygenated in rice organs. However, the \(O_2\)-dissociation rate constants of rice Hb1 and 2 (\(k_{O_2} = 0.038\) s\(^{-1}\)) \(91\), and possibly that of rice Hb3 and 4, are extremely low. These data do not support the \(O_2\)-transport function for rice Hb1 to 4 because these proteins would not release \(O_2\) after oxygenation. In contrast, the predicted kinetic constants for rice Hb5 and tHb suggest that these proteins bind and release \(O_2\) easily and thus that they function by transporting \(O_2\).

It was reported that hexacoordinate Hbs interact with either organic molecules or protein partners \(91,98\) and thus a possibility is that such interactions could impact the kinetic constants, particularly the \(O_2\)-dissociation rate constants, of hexacoordinate nsHbs \(96\). There have been no direct biochemical evaluations of this hypothesis in rice or in other plants, precluding definitive answers. However, their unique structural features could result in as yet undiscovered interactions.

Rice Hbs may function in \(O_2\)-signaling if they easily bind and release \(O_2\). Appleby and co-workers’ proposed that under normal conditions Hbs would be oxygenated and under \(O_2\)-limiting conditions the concentration of deoxyHb would increase triggering an anaerobic response. It was reported that levels of Hbs increase in rice roots from flooded plants indicating that the synthesis of rice Hbs increases under \(O_2\)-limiting conditions \(92\). Rice is a flooding resistant crop, thus under flooding (i.e. hypoxia) conditions rice Hbs could sense low \(O_2\)-concentrations and trigger an anaerobic metabolism for rice growth. To act as a signaling molecule, rice Hbs will need to bind directly to the DNA, to additional proteins, such as transcription factors, or catalyze some unique reactions that
can influence key downstream events. To date there are no reports of immunoprecipitation experiments specially targeting rice Hbs coupled to further proteomic analysis. It is thus uncertain if rice Hbs bind to other partners. There is also no structural evidence that indicates that rice Hbs can bind directly to DNA. In planta, they appear to be soluble and essentially contained within the cytoplasm. There are reports of nuclear-localized Hbs, but no direct evidence for a function arising from translocation of Hbs from the cytoplasm to the nucleus currently exist.

The NO dioxygenase activity exhibited by Hbs is well documented. NO is a hormone-like radical that modulates several aspects of the plant physiology, including plant immunity, seed germination, de-etiolation, apoptosis, stomata guard cells opening/closure and the rhizobia-legume symbiosis. Scavenging of NO is considered a function of plant Hbs. During this process, oxygenated plant Hbs react with NO producing nitrate and oxidizing ferrous Hb to the ferric form. Ferric plant Hbs are subsequently reduced to ferrous Hb by enzymatic and non-enzymatic mechanisms. This process regenerates ferrous Hb which is able to bind NO in a cyclic pathway referred to as the Hb/NO cycle. The operation of this cycle appears to be involved in maintaining an active metabolism in the plant cells. Rice Hb1 exhibits NO dioxygenase activity (k_{cat}/K_{m} = 90 s^{-1} M^{-1}) thus a possible function of Hbs into the rice physiology is modulating levels of NO by scavenging NO. However, the inability of rice Hb1 to substitute the NO scavenger activity in a flavoHb knockout Escherichia coli and the observation that levels of Hbs did not change in rice seeds germinated under nitrosative stress suggest that the NO dioxygenase activity of rice Hbs is limited in vivo.

A consequence of the operation of the Hbs/NO cycle could be the maintenance of cell respiration and energy status. Based on the studies on over- and under-expressing barley nshb in maize cells, it was proposed that under hypoxic conditions barley nshb is involved in the ATP metabolism, particularly in maintaining the energy status under O_{2}-limiting conditions. Immunolocalization data showed that rice Hbs are localized in differentiating cells (see subsection on Gene expression and localization of hemoglobins in rice organs). The metabolism of these cells is redirected in response to differentiation signals, such as a change in the cell redox state. Rice Hbs could be involved in redox signaling if the redox state of the heme is functional. Thus, under these conditions rice Hbs may function by sensing or maintaining redox environments that promote specific cell metabolisms.

It was proposed that one of the functions of plant Hbs could be related to the peroxidase activity. This is of interest because peroxidase activity modulates the levels of reactive oxygen species and a variety of cellular processes. Arabidopsis Hbs (AtGLB1, AtGLB2 and AtGLB3) revealed that these proteins oxidize Amplex Red, DHR123 and guaiacol substrates and overexpression of AtGLB1 increased tolerance of Arabidopsis to H_{2}O_{2} stress. These observations suggested that Arabidopsis Hbs function as antioxidants. However, levels of Hb polypeptides did not change in rice seeds germinated under H_{2}O_{2} stress. Also, the analysis of the peroxidase activity of rice Hb1 compared to that from horseradish peroxidase (HRP) showed that the catalytic efficiency of rice Hb1 for the oxidation of guaiacol using H_{2}O_{2} as electron donor is several orders of magnitude lower than that of HRP (k_{cat}/K_{m} = 15.8 and 44,833 mM^{-1} min^{-1}, respectively). Additionally, it was observed that recombinant rice Hb1 poorly protects E. coli from H_{2}O_{2} stress. This evidence indicates that it is unlikely that rice Hbs function in vivo as peroxidases.

Based on gene expression (Table 1), protein localization and structural and kinetic properties of rice Hbs and data from the analysis of other plant and non-plant Hbs it is likely that Hbs play a variety of roles in rice plants growing under normal and stressed conditions. These functions may include O_{2}-transport, O_{2}-sensing, NO-scavenging and redox-signaling. Future work on rice Hbs should focus on testing the above potential functions as well as newly proposed functions that emerge from novel observations.

**Evolution of rice hemoglobins**

Hbs are widely distributed in land plants, ranging from primitive bryophytes to evolved angiosperms. The outline of plant Hb evolution subsequent to land colonization was clarified. Briefly, a phylogenetic analysis showed that plant and animal hb genes diverged 900-1,400 mya, that land plant nshb and hb genes vertically evolved through different lineages from algal ancestors, that nshb-1 and nshb-2 are monophyletic and evolved via a gene duplication event prior to the divergence of monocots and dicots at ca. 140 mya, and that symbiotic hbs originated from nshb genes at ca. 94 mya. Likewise, the structural analysis of primitive nshbs and Lbs revealed that changes during the evolution of nshbs to Lbs were a hexacoor.

In contrast, the evolution of rice Hbs is partially understood owing to the limited availability of Hb sequences from a wide variety of wild and cultivated rice. However, the outline of monocot Hb evolution is rather well understood. Thus, in this section we will discuss the evolution of rice Hbs within the context of major events that occurred during the evolution of monocot Hbs. A major event during the evolution of land plant nshbs was the duplication of an ancestral nshb into nshb-1 and nshb-2 prior to the monocot-dicot divergence. Sequence analysis revealed that nshb-1 and nshb-2 genes exist in dicots and that apparently only nshb-1 genes exist in monocots. Earlier Garrocho-Villegas and co-workers reported the existence of a nshb (Hb5) divergent from rice (Hb1 to 4) nshbs-1 and suggested that nshbs divergent from nshbs-1 evolved within monocots. Subsequent phylogenetic analysis of monocot nshb sequences revealed that apparently only nshb-1 evolved within monocots, that nshb-1 duplicated early in the evolution of monocots originating clade I and clade II nshbs (nshbs-1 and nshbs-II, respectively), that nshbs-I correspond to dicot nshbs-1, and that nshbs-II diverged into regular nshbs-II, post-helix H-containing nshbs-II and 11 amino acids deletion-containing nshbs-II. This analysis also showed that O. sativa var. indica and O. sativa var. japonica Hb1 to 4 and Hb5 cluster within clade I and clade II, respectively, and that O. glaberrima and O. rufipogon (whose all nshb copies remain unidentified because their genome sequencing is in progress) nshbs cluster within clade I. Thus, apparently clade I and clade II lineages remain conserved during the evolution of rice nshbs.
Evaluation of the rate of divergence of selected land plant Hbs revealed that evolutionary rates slowed down previous to the origin of magnoliophyta and that the rate of divergence was slower in rice Hb1 than in rice tHb [31]. This observation suggested that rice Hb1 (and conceivably other rice nsHbs) evolved under the effect of the stabilizing selection. However, the estimation of the variability of the O. sativa var. indica, O. sativa var. japonica, O. glaberrima and O. rufipogon nsHb and tHb genes revealed that in these plants variability is higher in nsHbs than in tHbs and that these genes evolved under the effect of neutral selection [31]. Currently the effect of rates of divergence and gene variability on the Hbs function during the rice evolution is not known.

Concluding remarks and future directions

In the preceding sections of this review we summarized major findings from the study of rice Hbs. This review also reveals some major lacunae in our ability to completely understand rice Hbs, more specifically the lack of information about the precise functions of Hbs in rice organs. The proposed functions for rice Hbs are mostly based on the analysis of other plant and non-plant Hbs. Thus, future work should evaluate the Hb activities (e.g. the NO-binding and -detoxifying activities) in either rice organs or rice cell cultures under a variety of growing conditions. Elucidating the functions of rice Hbs also requires the identification of either homo- or heterodimeric rice Hbs and possible organic molecules and protein partners that interact with rice Hbs. Other lacunae are the absence of biochemical, biophysical and cellular data on the properties of rice Hb2 to 5 and Hb. Generating recombinant rice Hb2 to 5 and Hb should provide Hb polypeptides for a variety of analyses that reveal the biochemical and biophysical properties of these proteins.

With the exception of rice hb2, a lacuna is the absence of experimental information about the cis-elements and trans-acting factors that regulate the expression of rice hsbs. This information may help to integrate the hb gene expression into the rice metabolisms, including those that are modulated by plant hormones.

A final lacuna is the incomplete understanding of the evolution of rice Hbs. Sequencing of the O. glaberrima and O. rufipogon genomes will be completed soon and most likely a number of rice genomes (including that of O. barthii) is postulated as the ancestor of O. glaberrima [32,33,34] will be sequenced within the near future. This will provide new Hb sequences for phylogenetic analysis and the understanding of the evolution of rice Hbs, including the identification of ancestral rice Hbs and the evaluation of the effect of rice domestication and breeding during the evolution of rice Hbs.

References

The manuscript “Rice (Oryza) hemoglobins” by Arredondo-Peter, Moran and Sarath reviews the current status of research on the group of proteins found within rice plants belonging to the hemoglobin (Hb) superfamily. There is growing interest in Hbs, particularly non-mammalian Hbs, owing to their potential role as mediators of reactive nitrogen molecules, such as nitric oxide. Such a review is welcome, as rice is an important cultivar and adaptation to stress during growth plays an important role in the survival of the plant. The review covers a wide range of relevant topics, such as phylogenetic aspects, cellular localization, and chemical properties.

Within this review, the literature on rice Hbs is covered thoroughly, as witnessed by the extensive bibliography that accompanies the manuscript. However, closer inspection of that bibliography reveals an underlying issue with this manuscript. Although over 150 citations are given, a minority of those papers reference research performed specifically on rice plant or rice Hbs. This is not meant as a slight against the authors, rather as an observation that current research on rice Hbs is still in its infancy and extensive literature on the topic simply does not exist. With that in mind we would suggest altering this manuscript to acknowledge this shortage of experimental evidence in the following ways.

- By far the majority of experimental evidence exists of Hb1, yet throughout the manuscript Hb1 is treated more-or-less equally to Hb2-Hb5. The authors should focus on Hb1 in presenting the available evidence, then in a separate section (perhaps “correlations to other Hb genes”) the authors could examine homology models and hypothetical behavior without the danger of having conjecture misinterpreted by the reader as published fact.

- tHb belongs to a separate class of Hbs than the other Hbs in rice (Hb1 through Hb5), and throughout the manuscript it is often treated as an afterthought. As an addendum to the above comment we would also suggest a separate section be reserved for tHb. Though little experiment information may be available for this protein, a short stand-alone section would be more informative than a series of trailing paragraphs.

- Great care must be taken by the authors when postulating biophysical characteristics of rice Hbs using only homology models based upon a single crystal structure. Simple variations in structure can carry significant changes in heme iron coordination, reactivity and binding affinity. If such conjecture is used in this manuscript it must be plainly stated with the caveat that this is not published fact, or experimental evidence.
Additional specific comments

1. To orient the reader it would be helpful to include a two-panel figure containing (a) the amino acid sequence alignment of Hbs 1 through 5 using Hb1 as the anchor, and (b) the alignment of tHb using Arabidopsis thaliana GLB3 as the anchor. In both panels, the differences between each Hb and Hb1 (a) or tHb and GLB3 (b) could be emphasized (e.g., with color). The secondary structure of Hb1 (a) and GLB3 (b) could be indicated as well. In the text the % sequence identity for the relevant pairs should be mentioned. In addition, are the japonica and indica sequences identical? Whether one or the other cultivar is used should be clearly indicated throughout the review (for example, in Figure 2).

2. Apoprotein folding pathways are discussed on page 7. An additional statement as to the biological relevance of the folding pathway and information about association with the heme (when, where) would be interesting.

3. In general, it is not possible to predict the thermodynamic or chemical properties of a heme protein based on its primary structure. The case of Parasponia andersonii and Trema tomentosa hemoglobins provides one illustration of the difficulty within the plant world. Predictions can be inaccurate even when a three-dimensional structure is available. This shortcoming of sequence analyses and modeling could be emphasized with a discussion of specific examples and used to advocate the need for additional hemoglobin research.

4. Reaction with nitric oxide is a likely function of many hemoglobins. According to the work of Gardner and colleagues, the NO dioxygenase reaction begins with the binding of dioxygen followed by combination with NO to produce nitrate. In this mechanism, binding of NO to the iron is not necessary. In this regard, the statement on page 3 (bottom left) should be clarified. Likewise, the Hb/NO cycle as proposed by Igamberdiev and Hill involves oxyHb. In contrast, the description on page 9 suggests that one turnover occurs with oxyHb, followed by formation of Hb-NO.

5. Speculations regarding the formation of homodimeric or heterodimeric structures should also be qualified, since the concentration of the hemoglobins (sub micromolar) appears to be much lower than the projected Kd (mM).

6. In the “Postulated functions” section, a proposal is made that Hb5 and tHb are O₂ transporters. Could the authors elaborate on this function? (Transport to what and for what purpose, and is it consistent with the cellular concentrations?)

7. Ligand binding is central to the function of hemoglobins. The “kinetic” section provides little such information while the second paragraph of the “Postulated functions” section offers numbers. It would be useful to consolidate the kinetic data with a table containing the measured equilibrium and rate constants for Hb1 and Hb2 (CO, NO, O₂), as published in various primary references (for example, reference 97), and for Hb relatives mentioned in the text.

Competing Interests: No competing interests were disclosed.

We have read this submission. We believe that we have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however we have significant reservations, as outlined above.
Author Response 29 Nov 2014

Raul Arredondo-Peter, Universidad Autonoma del Estado de Morelos, Mexico

We thank Drs. Lecomte and Johnson for evaluating the first version of this review and for providing useful comments and suggestions. We agree with them and incorporated the suggested changes into the revised version of the review.

Competing Interests: No competing interests were disclosed.

Referee Report 13 November 2014

Martino Bolognesi
Department of Biosciences, University of Milan, Milan, Italy

The Review by Arredondo-Peter et al. presents our current knowledge on the fascinating field of plant non-symbiotic (nsHb) and truncated hemoglobins (tHb), for which substantial, but scattered, information has accumulated over the past twenty years. The Review deals specifically with rice Hbs. Work from several distinct worldwide groups has so far provided information on the gene families for five nsHbs, and for a single tHb in rice; moreover, expressed proteins have been located to various plant organs and developmental stages. Crystal structures and kinetic analyses have helped delineating the potential roles of rice Hbs in plant physiology, highlighting different O$_2$ binding affinities that differentiate the various Hbs.

A main question that remains unanswered concerns the in vivo functions carried over by the five distinct rice nsHbs and tHb; hints reviewed from the literature include O$_2$ sensing, signaling, O$_2$ transport, NO scavenging, and NO dioxygenase pseudo-enzymatic activities (others may also be plausible). The Review includes evolutionary considerations (and the effects of rice selection through domestication) that will be reinforced by the forthcoming completion of rice genomes.

Overall, the Review provides a useful compendium over a subject whose reunification into a coherent presentation will indeed support deeper exploration of the functional aspects, whose scientific and practical relevance cannot be underestimated.

Competing Interests: No competing interests were disclosed.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Author Response 16 Nov 2014

Raul Arredondo-Peter, Universidad Autonoma del Estado de Morelos, Mexico

We thank Dr. Bolognesi for evaluating this review and his comments.

Competing Interests: No competing interests were disclosed.
The benefits of publishing with F1000Research:

- Your article is published within days, with no editorial bias
- You can publish traditional articles, null/negative results, case reports, data notes and more
- The peer review process is transparent and collaborative
- Your article is indexed in PubMed after passing peer review
- Dedicated customer support at every stage

For pre-submission enquiries, contact research@f1000.com
