Abstract

Objective: Current practice mandates a prostate biopsy for histological confirmation of prostate cancer prior to a radical prostatectomy. Prostate biopsy, whether performed trans-rectally or trans-perineally, is an invasive procedure which typically involves anaesthesia and has the risks of urosepsis, bleeding and haematoma. Post-biopsy inflammatory changes can also obliterate natural tissue planes thereby potentially compromising the quality of a nerve sparing procedure and increasing positive margin rates.

3T-Multi-Parametric Magnetic Resonance Imaging of the Prostate (3T mpMRI-P) is gaining increasing acceptance in the identification and localisation of prostate cancer. In experienced centres, the positive predictive value has been reported to be as high as 95%.

Methods: Two patients with rising and elevated age-adjusted PSAs and palpable malignant prostate nodules on Digital Rectal Examination (DRE) underwent 3T mpMRI-P. Both patients had Prostate Imaging-Reporting and Data System (PI-RADS) 5 lesions in their peripheral zones corresponding to palpable nodules. Prostate biopsies were offered but declined by both patients. Both were satisfied that there was sufficient evidence on their PSA, DRE and 3T mpMRI-P for a diagnosis of prostate cancer without prostate biopsies and both elected to proceed to a Da Vinci Robotic Assisted Laparoscopic Radical Prostatectomy (RALRP).

Results: Unilateral nerve sparing RALRPs were performed on both patients without complication. Histology demonstrated Gleason 4+4=8 and 4+3=7 prostate adenocarcinomas, with tumour volumes of 14.92cc and 4.5cc respectively.

Conclusions: In appropriately counselled patients who have a high pre-test probability of prostate cancer (rising and elevated PSA, malignant nodule on DRE and a corresponding PI-RADS 5 lesion on 3T mpMRI-P), it may be appropriate to proceed to a radical prostatectomy without a tissue diagnosis if the patients have strong reservations about prostate biopsy.

Introduction
Current practice mandates a prostate biopsy for histological confirmation of prostate cancer prior to a radical prostatectomy. Prostate biopsy, whether performed trans-rectally or trans-perineally, is an invasive procedure which usually requires an anaesthetic and has the inherent risks of urosepsis, urinary retention and haematoma\(^1\). Post-biopsy inflammatory changes can also obliterate natural tissue planes there by potentially compromising the quality of a nerve sparing procedure and increase positive margin rates\(^3\). For this reason prostatectomy is usually delayed by at least 6 weeks to allow for a reduction in the peri-prostatic inflammatory change that follows any biopsy procedure\(^4\).

The use of 3T mpMRI-p is gaining increasing acceptance for both the diagnosis and localisation of prostate cancer. In experienced centres, the positive predictive value of Prostate Imaging-Reporting and Data System (PI-RADS) 5 lesions has a specificity of 97–100% in biopsy naïve patients\(^5\)\(^–\)\(^8\). We describe two case reports of radical prostatectomy without tissue diagnosis. The patients involved both had objections to confirmative biopsy, PI-RADS 5 lesions on mpMRI-p and high pre-test probabilities of prostatic malignancy. We believe this report will be of interest for urologists dealing with the dilemma of patients with a high risk of prostatic malignancy, positive mpMRI-p and patient refusal of biopsy procedures.

Case 1
A 56 year old man was referred to our service with elevated Prostate Specific Antigen (PSA) titres, which had risen progressively from 1.7 ng/mL to 4.6 ng/mL over a five year period. He had a positive family history of prostate cancer (PC), with his brother having undergone radical prostatectomy 5 years earlier. His digital rectal exam (DRE) showed a malignant nodule in his right lobe and a firm contralateral lobe.

We requested a 3-Tesla Multi-parametric Magnetic Resonance Imaging of the prostate (mpMRI-p) which identified a Prostate Imaging-Reporting and Data System (PI-RADS) 5 lesion in the right lobe of the prostate with probable extra-prostatic extension (Figure 1). A smaller lesion was present in the left mid peripheral zone (Figure 2) with possible left external iliac node involvement. Staging Computerised Tomography (CT) of the abdomen and pelvis and Tc-99m bone scan showed no radiological evidence of metastatic spread other than the previously mentioned borderline enlarged left external iliac nodes.

The results of the investigations (PSA titres, DRE) and the chance of a false positive mpMRI-p result of approximately 5% was explained to the patient. The patient was adamantly against undergoing confirmatory prostate biopsy as he was concerned about biopsy related sepsis. He also reported pre-existing anxiety regarding PC since his brother had been diagnosed and treated.

The patient subsequently underwent a bilateral incremental nerve sparing Robot Assisted Laparoscopic Radical Prostatectomy (RALRP) with left sided extended pelvic lymph node dissection.

Figure 1. Patient 1: Axial T2 weighted MR showing large posterior hypo-intense lesion with EPE.

Figure 2. Patient 1: Apparent Diffusion Co-efficient (ADC) map, showing bilateral posterior lesions (arrowheads) and bilateral mid zone lesions (arrows).

The Operative specimen’s histology demonstrated Gleason 4+3=7 primary tumour with tertiary pattern 5 present (Figure 3) with extraprostatic extension (EPE) present. Peri-neural invasion was present (Figure 4). A focally positive margin at region of EPE was present over a 0.5 mm base. The specimen’s histological stage was T3a (AJCC 7th Edition 2010).

The patient made an uneventful recovery from surgery. Post-operative incontinence was mild at 6 weeks, using a single safety pad during the day only. He is trialling sildenafil for his post-operative erectile dysfunction. His PSA at 5 weeks was low at 0.033 ng/mL. His follow-up is ongoing.
Case 2
A 64 year old with no family history of prostate cancer and an elevated serum PSA of 9 ng/mL was refereed to our service. His DRE revealed a right sided palpable prostate nodule with extension into the ipsilateral seminal vesicle.

mpMRI-p was requested and confirmed a PI-RADS 5 lesion in the right base and mid-zone of the gland (Figure 5). The lesion extended across midline into the left lobe. Diffusion restriction was present on ADC map (Figure 6). Right-sided seminal vesicle invasion was also demonstrated radiologically (Figure 7).

The patient was advised to undergo confirmatory prostate biopsy but declined, being satisfied with his diagnosis based on PSA, DRE and Mp-MRI-p findings. CT and Tc-99m bone scans were negative for metastatic spread.

The patient underwent RALRP. Due to his seminal vesicle invasion a wide non-nerve sparing approach was taken on the right side, with the contralateral nerve bundle spared due to the patient being sexually active. A right sided obturator node dissection was performed concurrently.

Histology demonstrated Gleason 4+4 with tertiary pattern 5 (Figure 8). Tumour volume was 14.92cc. Right neurovascular bundle invasion and bilateral seminal vesicle invasion was present (Figure 9). All resection margins were uninvolved and 0/3 resected.
post-operatively it had risen further to 0.14 ng/mL. He was subsequently referred to radiation oncology for salvage radiotherapy for biochemical failure.

Discussion
Both patients in our small case series were diagnosed and their tumours correctly localised by mpMRI-p. Whilst we strongly recommended both patients proceeded to confirmative prostate biopsies, they both declined further investigation. Both patients had high pre-test probabilities of malignancy even prior to their positive mpMRI-p findings and were satisfied that their diagnoses were correct, and had concerns about the risks of prostate biopsy. They were both informed of and willing to accept the small risk of a false positive diagnosis.

It is important to note that radical prostatectomy without tissue diagnosis is not recommended as standard practice by the authors, even with a PI-RADS 5 lesion on mp-MRI-p. The case studies presented here are exceptional cases where both patients had strong opposition to biopsy despite counselling otherwise. Whilst mpMRI-p has demonstrated great sensitivity and specificity for identification of high risk prostate cancer, there remains the possibility of over diagnosis, and consequent overtreatment if a confirmatory biopsy is not also obtained pre-operatively. With further development of this imaging technology it is plausible that in the future, high risk patients with PI-RADS 5 lesions on mpMRI-p could undergo a radical prostatectomy without the need for a prostate biopsy. While we have successfully performed two prostatectomies without pre-operative biopsy we do not advocate this as a standard approach.

Conclusion
In exceptional circumstances and with appropriately counselled patients who have a high pre-test probability of prostate cancer (rising and elevated PSA, malignant nodule on DRE and a corresponding

PIRADS 5 lesion on mpMRI-P), it may be appropriate to proceed to a radical prostatectomy without a prostate biopsy. Further advancements in mpMRI-p imaging techniques may negate the need for routine biopsies in high risk lesions prior to prostatectomy, but this cannot be recommended as routine practice with currently available imaging protocols.

Consent
Written informed consent for publication of their clinical details and clinical images was obtained from the patients.

In this case report the authors describe two cases of patients highly suspicious for prostate cancer based on PSA levels, physical examination and MRI who underwent surgery and the final pathology coincided with the presumed diagnosis.

It is not clear what is the benefit of undergoing major surgery without confirmed diagnosis, on the contrary, today we are moving forward and advocating for tissue diagnosis prior to oncological surgery.

If the MRI is highly suspicious for tumor one can advocate for MRI/US fusion biopsy and reducing the number of cores taken to a minimum.

Competing Interests: No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard, however I have significant reservations, as outlined above.

Author Response 13 Jul 2015

Andrew Keller, Wesley Research Institute, Auchenflower, Australia

Thanks for your comments Dr. Lindner.

Whilst there are a few potential benefits for undertaking major surgery without first obtaining histo-pathological diagnosis (zero risk of biopsy related sepsis, no obliteration of tissue planes by post-biopsy inflammation) the authors do not argue that those benefits outweigh the risk of a false diagnosis. Indeed, the benefits of tissue confirmation of malignancy prior to a potentially morbid procedure such as prostatectomy cannot be understated. Instead, this article describes two cases where both patients had significant anxiety regarding their potential diagnosis of prostate cancer.
Both patients were counselled on the potential false positive rate of mp-MRI-p and were counselled to have their clinical diagnosis confirmed via biopsy but both declined. Such was their anxiety despite reassurances from the surgeon, that both patients insisted on prostatectomy despite being warned of the risk of potentially benign operative histology. It is possible that even negative pre-operative biopsy might not have allayed their concern.

It must be emphasized that the authors do not advocate prostatectomy without biopsy as standard practice. The current specificity of mp-MRI-p is insufficient for confident diagnosis without confirmatory biopsy. In these cases, however, where due to patient factors biopsy was not possible, mp-MRI-p was invaluable in correctly identifying tumour location in order to facilitate prostatectomy.

**Competing Interests:** No competing interests were disclosed.
Dr. Ather, thanks for your comments.

I agree with you that while the new imaging technologies are exciting that diagnosis should remain, for the most part histological. These two cases were the exceptions to the rule, and due to patient, rather than surgeon preference.

In regards to your comments, whilst pain can certainly be controlled in the TRUS setting with use of twilight sedation, our experience is that even with more intensive regimens of antibiotics the rates of TRUS sepsis are increasing, mostly due to increased prevalence of ciprofloxacin-resistant E. Coli.

Secondly, both patients did give informed consent for the prostatectomy, including very clearly being told that there was a chance of a false positive diagnosis from the MR scanning. There are numerous examples of legal action in spite of informed consent of risks and I can see certain patients suing in the event of benign pathology.
