**Abstract**

*Helicobacter pylori* is a gastric pathogen that causes several gastroduodenal disorders such as peptic ulcer disease and gastric cancer. Eradication efforts of *H. pylori* are often hampered by antimicrobial resistance in many countries, including Vietnam. Here, the study aimed to investigate the occurrence of antimicrobial resistance among *H. pylori* clinical isolates across 13 hospitals in Vietnam. The study further evaluated the clarithromycin resistance patterns of *H. pylori* strains. In order to address the study interests, antimicrobial susceptibility testing, epsilometer test and PCR-based sequencing were performed on a total of 193 strains isolated from patients, including 136 children (3–15 years of age) and 57 adults (19–69 years of age). Antimicrobial susceptibility testing showed that the overall resistance to amoxicillin, clarithromycin, levofloxacin, metronidazole, and tetracycline was 10.4%, 85.5%, 24.4%, 37.8%, and 23.8% respectively. The distribution of minimum inhibitory concentrations (MICs) of clarithromycin-resistant strains was 85.5% with MIC >0.5 μg/mL. The majority of the clarithromycin resistant isolates (135 of 165 subjects) have MICs ranging from 2 μg/mL to 16 μg/mL. Furthermore, sequencing detection of mutations in 23S rRNA gene revealed that strains resistant and susceptible to clarithromycin contained both A2143G and T2182C mutations. Of all isolates, eight clarithromycin-resistant isolates (MIC >0.5 μg/mL) had no mutations in the 23S rRNA gene. Collectively, these results demonstrated that a proportion of clarithromycin-resistant *H. pylori* strains, which are not related to the 23S rRNA gene mutations, could be potentially related to other mechanisms such as the presence of an efflux pump or polymorphisms in the CYP2C19 gene. Therefore, the present study
suggests that providing susceptibility testing prior to treatment or alternative screening strategies for antimicrobial resistance is important for future clinical practice. Further studies on clinical guidelines and treatment efficacy are pivotal for successful eradication of \textit{H. pylori} infection.

This article is included in the Antimicrobial Resistance collection.
**Introduction**

*Helicobacter pylori* is a Gram-negative bacterium that plays a causative role in the development of gastric adenocarcinoma, peptic ulcer disease and chronic gastritis. The prevalence of *H. pylori* infection is more than half of the world’s population, comprising of >80% in developing countries and approximately 40% in the United States. In Vietnam, the prevalence of *H. pylori* is approximately 80% in adults and 26%–71.4% in children.

Eradication therapy of symptomatic *H. pylori* infection substantially prevents the recurrence and reduces the risk of developing gastroduodenal-associated diseases. Recommended therapy, triple-therapy regimen, composed of two antimicrobial agents (e.g. amoxicillin, metronidazole, tetracycline, levofloxacin, and clarithromycin) in combination with a proton pump inhibitor (PPI), has been widely used to eliminate the bacteria. However, *H. pylori* antimicrobial resistance is increasing worldwide, contributing to the main factor that affects the efficacy of current therapeutic regimens. Resistance to clarithromycin is believed to be the main factor in treatment failure. In Vietnam, many studies showed that *H. pylori* is highly resistant to clarithromycin; 33%–34% primary and 74% secondary resistance. The majority of clarithromycin-resistant strains are identified based on point mutations in the peptidyltransferase region of domain V of 23S rRNA, which affects the binding of macrolides to the bacterial ribosome.

The common 23S rRNA point mutations (e.g. A2143G, A2142C/G and T2182C) are recommended for rapid routine diagnostic procedures, as compared to the time-consuming bacterial culture. A plethora of studies have evidently reported the association of minimum inhibitory concentrations (MICs) of clarithromycin-resistant strains to the respective point mutation. For example, A2142C/G mutations are associated with MIC >256 μg/mL, and mutations such as A2143G and T2182C are associated with MIC >0.5 μg/mL. However, it is unclear whether such association between point mutation and MIC can be utilised as predictors for strains resistant to clarithromycin. Here, the present study evaluated the antimicrobial resistance of *H. pylori* strains isolated from patients in Vietnam with the following antimicrobial agents: amoxicillin, metronidazole, tetracycline, levofloxacin and clarithromycin.

PCR amplification and sequence detection of 23S rRNA mutation

The PCR mixture (20-μL final volume) contained HotStar Taq master mix (Qiagen, Hilden, Germany) and 10 pmol of forward DP1 (5’-GTAAACACGACGGCCAGTCACGCGCCGTACTAGTA-3’) and reverse ZGE23 (5’-TTTTTGGGTAGCTATAGACAGGCCAGTTAGCTA-3’) primers. These primers contain sequences (written in bold-faced type) that are specific for SP6 (DP1) and M13 (ZGE23), and underlined sequences indicate 23S rRNA amplicon of 308 bp comprising of 2142, 2143 and 2182 positions. The *H. pylori* colonies on selective medium was added to 1x TE buffer (10 mM Tris- HCL, 1 mM EDTA, pH 7.6) and heated up to 100°C for 5 min, followed by centrifugation at 8000 rpm. 1 μL of supernatant was added to the PCR mix to amplify 23S rRNA gene and M13 resistance (MIC >0.5 μg/mL).
Antimicrobial resistance of *Helicobacter pylori* isolates

To assess the antimicrobial resistance of *H. pylori* in Vietnam, susceptibility testing was performed and the resistance rate of each antimicrobial is listed in Table 1. The prevalence of antimicrobial resistance was detected in the following order, from highest to lowest: clarithromycin, metronidazole, levofloxacin, tetracycline and amoxicillin. Of all the antimicrobial agents, the majority of isolates were resistant to clarithromycin as shown in 85.5% of all patients (84.6% in children and 87.7% in adults). The occurrence of metronidazole resistance was lower than clarithromycin (overall 37.8% vs. 85.5%) in this study, as compared to the other published reports. 14 (24.6%) of all isolates were resistant to clarithromycin as shown in 85.5% of all patients (84.6% in children and 87.7% in adults). The occurrence of metronidazole, and tetracycline in both children and adults. Among the antimicrobial agents, clinical isolates resistant to levofloxacin is significantly higher ($p = 0.0103$) in adults than in children.

Minimum inhibitory concentration values of clarithromycin-resistant isolates predominately range from 2 μg/ml to 16 μg/ml.

To validate the clarithromycin resistant isolates, MIC values were obtained from a total of 193 clinical isolates using an E-test. Based on EUCAST proposed breakpoints, the respective occurrence of clarithromycin susceptible and resistant isolates was 24 (12.4%) and 165 (85.5%) of the total number of isolates used in this study. The distribution of MICs showed that the majority of clinical isolates resistant to clarithromycin (135 of 165 isolates, 81.8%, including 97 children and 38 adults) ranged from 2 μg/mL to 16 μg/mL.

Figure 1. Antimicrobial resistance rate of *Helicobacter pylori* isolates from Vietnamese children and adults. The graph displays the resistance rate of amoxicillin, clarithromycin, levofloxacin, metronidazole, and tetracycline in both children and adults. Among the antimicrobial agents, clinical isolates resistant to levofloxacin is significantly higher ($p = 0.0103$) in adults than in children.

Mutations of 23S rRNA gene in *Helicobacter pylori* isolates

To investigate the point mutations in the 23S rRNA gene of clarithromycin-resistant isolates, mutations at position 2142 (A2142G or A2142C), 2143 (A2143G), and 2182 (T2182C) were analysed in this study. Sequence analyses showed the point mutations in the 23S rRNA gene were detected not only in clarithromycin-resistant isolates, but also in clarithromycin-susceptible isolates. In Table 2, both A2143G and T2182C mutations were predominantly detected in 91.7% ($n = 177$) of the clarithromycin-susceptible and –resistant isolates. Only two clarithromycin-resistant isolates in adults had the A2142G and T2182C mutations with a respective MIC value of 8 μg/mL and >256 μg/mL. In addition, a total of 10 clarithromycin-resistant and –susceptible isolates had no mutations in the 23S rRNA gene. The present study also identified four isolates with both A2143G and T2182C mutations at MIC values ranging from 0.38 to 0.5 μg/mL, which are considered to be intermediate resistance strains.

**Discussion**

Antimicrobial resistance in *H. pylori* has become a global health problem because the prevalence of infection and incidence is increasing worldwide. The increasing *H. pylori* resistance to antimicrobial agents, such as clarithromycin, is considered the main
Figure 2. Minimum inhibitory concentration values of clarithromycin susceptible and resistant isolates in children and adults.

The graph shows the number of isolates across a range of minimum inhibitory concentration values of clarithromycin. The total number of clarithromycin susceptible and resistant isolates is 24 and 165, respectively. Majority of clinical isolates resistant to clarithromycin have MIC values ranging from 2 μg/mL to 16 μg/mL.

** indicates H. pylori isolates with A2143G and T2182C mutation at MIC values, which are considered to be intermediate resistance strains.

Abbreviations: ‘N.A.’ – not applicable; ‘S’ – susceptible; ‘R’ – resistance.

The high incidence of *H. pylori* strains resistant to clarithromycin and metronidazole in Vietnam might be attributed to the following: (i) unregulated or widespread over-the-counter use of antibiotics, (ii) clarithromycin is prescribed frequently for treatment due to its high bactericidal effect, and (iii) antibiotics are often used to treat *H. pylori* infection and other infections including respiratory tract infections (clarithromycin) and intestinal parasites (metronidazole).

Vietnam is categorised as a region with a high prevalence of *H. pylori* infection and an intermediate risk of gastric cancer. Therefore, the understanding of geographical region specific prevalence is crucial for treatment of *H. pylori* infection.

Vietnam is categorised as a region with a high prevalence of *H. pylori* infection and an intermediate risk of gastric cancer. Therefore, the understanding of geographical region specific prevalence is crucial for treatment of *H. pylori* infection. Our present study showed that the overall resistance rate for clarithromycin and metronidazole was 85.5% and 37.8%, respectively.
in Vietnam. The observation of high clarithromycin resistance rate from our data suggested the increasing occurrence of resistant strains among other antimicrobial agents. Therefore, constant surveillance for antimicrobial resistance rates is necessary to gain insights into effective eradication therapy of H. pylori infection.

Another interest of this study was to assess the variations of MIC values obtained from the clarithromycin-resistant strains. Our representative clinical isolates obtained from the gastric mucosa revealed that the majority of strains resistant to clarithromycin conferred MIC values ranging from 2 μg/mL to 16 μg/mL. There is also a degree of variation on the MIC range between studies. The variability of MIC values for resistant isolates might be attributed to different gastric sites. The evidence is supported by Borody et al. who demonstrated that the bimodal distribution of clarithromycin resistance of isolates cultured from 4 gastric sites (i.e. antrum, distal body, proximal body and fundus) ranged from <0.016 μg/mL to 256 μg/mL. The recent studies also demonstrated that MIC values for clarithromycin resistance vary at different gastric sites. Therefore, the present results confirm previous studies that multiple gastric biopsies from different sites of the stomach are crucial for accurate diagnosis of H. pylori infection.

Furthermore, antimicrobial susceptibility testing using MIC values is often used to determine the appropriate dosage of antimicrobial for a patient’s prescription. However, the respective antimicrobial resistance rate is based on the defined MIC breakpoints, which are much lower than the achievable tissue concentrations of antimicrobial agents such as clarithromycin (ranging from 5.2 μg/mL to 22.2 μg/mL). Only a few studies have reported the eradication rate of H. pylori infection with high MIC values (e.g. >24 μg/mL), highlighting that the significant eradication rate of 50%–80% on MIC-defined resistant strains can be achieved by administering PPI with precise antibiotic dosage and appropriate treatment duration. Hence, further longitudinal studies on treatment efficacy and treatment guidelines are necessary for successful treatment.

Point mutations at positions 2142, 2143 and 2182 on the 23S rRNA gene were commonly reported. Yet it remains unclear whether or not these point mutations could be a strong predictor of clarithromycin resistance. In some studies, only the A2142G mutation was found to be associated with high MIC values. While other studies showed that mutations at positions 2142 and/or 2143 were associated with clarithromycin resistance. In addition, mutation T2182C was only reported in one study. Here, we reported that H. pylori strains with mutations in A2143G and T2182C exhibited not only in clarithromycin-resistant strains, but also in susceptible strains as observed in Table 2. Similar to Phan et al.’s study, none of the clarithromycin-resistant strains portrayed A2142C mutation in our study. It is important to note that the association of MIC values and point mutations was not confirmed in our study. Additionally, a proportion of all isolates had no point mutations in the 23S rRNA gene (Table 2). Further investigation on other nucleotide positions of the 23S rRNA region should be performed on these resistant strains. Additionally, we suggested that a proportion of these resistant strains, which are not related to the 23S rRNA gene sequence, could be potentially related to other mechanisms such as the presence of an efflux pump (e.g. outer membrane protein hefA) or polymorphisms in the CYP2C19 gene.

Conclusions
In conclusion, our present results confirm that MIC values are critical for accurate identification of antimicrobial resistant strains. Susceptibility tests prior to treatment are necessary to select the optimal H. pylori therapy regimens in Vietnam. Further studies on other resistance mechanisms, particularly the mutations of the host genes, will provide additional insights into the development of diagnostic biomarkers and therapeutic drugs.

Consent
Written informed consent for publication of their clinical details was obtained from the parents of the patients.

In general this is an interesting paper reporting on resistance of the antibiotic clarithromycin in Vietnam and the relevance of this resistance to Helicobacter pylori infection. The main outcome of this work is that it demonstrates the need for susceptibility testing prior to treatment. It is encouraging that this work is led by Vietnamese scientists and the work appears of a high standard.

It would have been useful to have a figure showing the mutational hotspots within the 23S rRNA gene.

General

Bacterial species names should be written in italics

The MICs stated on page 3 (3rd para) show considerable variation with a large range, i.e., >256 mg/ml and >0.5 mg/ml. What is considered significant?

MIC should be used as an abbreviation in Figures and Tables as well as text, e.g. Fig 2 and Table 2

Competing Interests: No competing interests were disclosed.

I confirm that I have read this submission and believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Reviewer Report 31 May 2016

https://doi.org/10.5256/f1000research.8861.r14071
This is one among the informative studies about the antimicrobial susceptibility and clarithromycin resistance patterns of Helicobacter pylori clinical isolates in Vietnam. The title is appropriate for the content. The methods and analysis of the results are well-described and appropriate.

However, there are several minor revisions that the authors should be considered to make results of the paper more clinically meaningful:

1. The design of this study is not prospective randomized one. It is a cross-sectional study.

2. The clinical information of the patients recruited in the study should be clarified: are they naïve patients or not. This information is essential to understand the true situation of antimicrobial susceptibility in Vietnam. As a result, the conclusion “Susceptibility tests prior to treatment are necessary to select the optimal H. pylori therapy regimens in Vietnam” may be not appropriate without this information.

3. The authors should also addressed the weak points of the studies. Although this is a multi-center study, all of the medical centers locates in southern Vietnam. The picture of antimicrobial susceptibility and clarithromycin resistance patterns of Helicobacter pylori has been shown to be somewhat different in Central and Northern Vietnam. Therefore, the author should change the title from “in Vietnam” to “in southern Vietnam”, or they can keep the title as it was but add a sentence which mentions this weak point of the study.

**Competing Interests:** No competing interests were disclosed.
