Abstract

Background: Health status is largely determined by socio-economic status. The general health of individuals at higher social hierarchy is better than people in lower levels. Likewise, people with higher socio-economic status have better oral health than lower socio-economic groups. There has not been much work regarding the influence of socio-economic status on the health conditions of children in developing countries, particularly in Iran. The aim of this study was to compare the oral and general health conditions of primary school children of three different socio-economic areas in the city of Shiraz, Iran.

Methods: This cross-sectional study was conducted on 335, 8- to 11-year-old primary schoolchildren in Shiraz. The children were selected by a three-stage cluster sampling method from three socio-economically different areas. Tools and methods used by the United Kingdom’s Medical Research Council were used to obtain anthropometric variables as indicators of general health. The Decay, Missing, Filled Teeth (DMFT) Index for permanent teeth, dmft Index for primary teeth, the Modified Developmental Defects of Enamel (DDE) Index, the Gingival Index (GI) and the Debris Index-Simplified (DI-S) were used for oral health assessment.

Results: Height (P<0.001), weight (P<0.001), and BMI (P=0.001) significantly increased as the socio-economic status of area increased. GI score (P<0.001), DI-S score (P<0.001), number of permanent teeth with DDE (P=0.008), and number of DDE lesions in permanent teeth (P=0.008) significantly decreased as the socio-economic status of area increased.

Discussion: Findings of this study generally confirmed that social gradients exist in both general and oral health status of the primary schoolchildren of Shiraz. The influence of socio-economic status on health condition means children have different life chances based on their socio-economic conditions. These findings emphasize the significance of interventions for tackling socio-economic inequalities in order to improve the health status of children in lower socio-economic areas.
Introduction

Health status is largely determined by social class and socioeconomic status. Understanding the association between socioeconomic status and health outcomes is of great importance for planning health promotion strategies. It is generally accepted that “there is a social gradient in health”1–4. In the national trend, the gradient is the status of an individual in socio-economic hierarchy and shows that people at the top of social hierarchy have better health than those in lower levels1. In the international trend, the gradient indicates more affluent countries have better health outcomes compared to poorer countries5.

The effect of socio-economic status is shown on a wide range of health outcomes from drug misuse related diseases6 to age-specific mortality6. A study on 6 to 11 year-old children of the United States found that social class had positive association with minor and major physical disorders such as colds, infections, allergies, diabetes, and even epilepsy6. The relationship between household income and a range of health outcomes in children and adolescents has been shown in Britain10. A study in France has found a significant positive correlation between family income and some of the most important child health indicators such as anthropometric measurements11.

In consistence with general health, social gradients are shown in oral health indicators. It seems that despite the remarkable improvements in the averages of oral health indices among communities in the last decades, inequities in oral health - mostly related to social inequalities - continue to exist12,13.

A study on the relationship between work conditions and health inequalities in Switzerland has found clear social gradients for almost all adverse working status and the outcomes of oral health14. In a case-control study in Mexico, lower socioeconomic status was identified as a risk factor for non-syndromic orofacial clefts15. Another study on Chinese 5-year-old children found that there were notable gradients in carious primary teeth related to their household income16. A study on young children of Salem, Tamil Nadu, India, showed that those from lower socio-economic groups, especially whose parents’ had lower education were more likely to suffer from Early Childhood Caries17. It was also shown that poor socio-economic background can be a strong predictor for poor oral hygiene18.

There has been limited evidence in Iran regarding the association between socio-economic status and general and oral health gradients, particularly among children. Therefore, this study was designed to assess the existence of social gradients in oral and general health of 8- to 11-year-old primary school children in three different socio-economic areas of Shiraz, a city in Southern Iran.

Material and methods

This cross-sectional study was conducted on 8- to 11-year-old children (third to fifth grade primary school children) of the city of Shiraz, Iran, in 2009. Approval and ethical permission were obtained from the National Ethical Committee in Medical Research of Iran (ID 85/p/3/1095). Permission to enter the selected schools was then obtained from the Educational Head Office of the Province of Fars (ID 17568/55). Based on the prevalence of Developmental Defects of Enamel (DDE) and a confidence level of 95%, a sample size of 335 was estimated appropriate for this study.

A three-stage cluster sampling approach was used to select the children. The main Educational Affairs Office of Shiraz had a category which divided the city into three areas based on socio-economic status: upper, middle, and lower social class areas. This kind of division seemed more appropriate for this study than any other division, such as geographically separated zones. One boys’ and one girls’ school (primary schools are segregated in Iran) were selected from each of the three socio-economically different areas. This was done by simple randomization using the list of primary schools in each area. Then, two classes were randomly selected in each school from the third, forth, and fifth grades. All children present in each selected class were included in the study, only if their parents provided written consent.

Although socio-economic differences between the three areas were well recognized by officials (Educational Head Office 2006), the number of parents having an occupation (any job), and the number of parents having a permanent occupation (as a job security indicator) were used as socio-economic related variables to compare the three areas and confirm the socio-economic difference between children chosen from these areas15,16. Related information was obtained from schools’ administration offices.

Height and weight are valuable indicators of present and past health status. Dividing the body height into trunk and leg length provides more precise information particularly on nutrition status of the early years of life19,20. Standing height, leg length, weight, and BMI (Body Mass Index) were used in this study as indicators of general health.

To obtain children’s height and weight, the tools and methods used by United Kingdom’s Medical Research Council were adopted20. For weight, a digital scale (Beurer Electronic Weight Scale PS 07, Germany) with accuracy of 100 grams was used. It was calibrated in each school. A wall mounted height meter with accuracy of millimetres was used for measuring children’s standing height. A similar metre adjusted to the seat of a chair was used to measure the length of the upper trunk, from head to the chair’s seat (sitting height). The leg length was calculated by deduction of the sitting height from the standing height. BMI was calculated by dividing the weight by the square of the standing height. Identically calibrated tools were used for all cases in all schools.

Assessment of dental caries, DDE and gingival health determined the oral health status of children. Clinical intra-oral examinations were carried out using WHO screening criteria to record data on Decay, Missing, and Filled Teeth (dmft) for the primary dentition and DMFT for the permanent dentition21. Permanent teeth were assessed from first molar to first molar in each arch. Therefore, second permanent molars, if present, were not assessed. DDEs of permanent teeth were recorded based on the Modified DDE Index22. Gingival health and oral hygiene were assessed using the Gingival Index (GI)23,24 and the Debris Index – Simplified (DI-S)25. All examinations were carried out in classrooms using natural light, disposable mirrors and tongue blades.
Normality of distribution of each outcome variable was assessed by a histogram. All continuous variables had a distribution close to normal. The difference between sexes was analysed by a t-test. Two socio-economic variables of number of parents with any occupation and with a permanent occupation were compared among the three areas using one-way ANOVA. Anthropometric measurements, gingival health, and oral hygiene status were also assessed among the three areas by one-way ANOVA. Anthropometric measurements (linear regression), gingival health status, and oral hygiene status (quantile regression) were also compared among the three areas after adjusting for sex and age. DMFT, dmft, number of teeth needed treatment, number of permanent teeth with DDE and total number of DDEs in children’s permanent dentition were compared between areas using Poisson regression model after adjusting for sex and age. Anthropometric measurements, gingival health, and oral hygiene status were also assessed among the three areas after adjusting for sex and age. 

The average number (± standard deviation) of present deciduous teeth was 6.2 (± 4.3). Number of permanent teeth present in the mouth ranged from four to 24 with an average of 16 fully erupted permanent teeth per child (Table 2). Number of present permanent teeth was significantly higher in girls (mean = 18.1) than in boys (mean = 13.6). The difference remained statistically significant after adjustment for age (P < 0.001). Forty nine percent (164) of children had a DDE. There was no difference between the percentages of boys and girls having a DDE in permanent teeth. Table 2 shows the number of permanent teeth with DDE and the total number of DDEs in permanent teeth. Both variables increased as socio-economic status of area decreased. The trends were statistically significant for number of permanent teeth with DDE (P = 0.018) and the total number of DDEs in permanent teeth (P = 0.025) after adjusting for number of present permanent teeth in the mouth. The significance levels increased (P = 0.008 for both variables) after adjusting for age and sex in the regression model.

The average dmft (of the primary dentition) was 2.8 ± 2.5. Three quarters of the cases (75.2%) had a dmft of 1 or more. The average DMFT (of the permanent dentition) was 1.22 ± 1.5. Almost half of the sample (47.5%) had caries experience in their permanent teeth. DMFT increased from 0.7 in 8-year-olds to 1.4 in 11-year-olds. Although the mean DMFT was higher in girls (1.3) than in boys (1.0) (P = 0.02), the difference was not significant after adjustments for age and number of permanent teeth (P = 0.42).

There was no statistically significant trend in DMFT or dmft among areas. Children in the middle class area had the highest
caries prevalence and highest need for treatment among all three areas. Although a clear path of social gradients was not observed, total number of teeth with treatment need was significantly lower in children in high socio-economic area compared with other children (P = 0.006). There was also a significant difference in mean number of deciduous teeth with treatment need between the high socio-economic area and the two other areas (P = 0.005) (Table 3).

A considerable number of children had gingival inflammation. Average GI score was 0.18 with only 82% of children being scored 0. The average DI-S was 0.52. The difference between the sexes was not statistically significant (P = 0.43 for GI and P = 0.44 for DI-S).

The gingival health significantly improved as the socio-economic status of area increased (P < 0.001). The significance did not change after adjustments for sex and age. There was also significant trend in oral hygiene status (P < 0.001). The number of children with dental plaque (P < 0.001), and also the average level of dental plaque in children (P < 0.001) decreased as the socio-economic status of area increased (Table 4).

Discussion

Findings of this study generally confirmed that social gradients exist in both general and oral health status of the primary school children of Shiraz. Children in lower socio-economic areas were shorter and lighter, and had shorter legs. In terms of oral health, socio-economic status had more effects on gingival inflammation, levels of plaque, and specially occurrence of DDEs, but was less related to dental caries experience and caries treatment need.

Most findings of this study were consistent with those of similar studies in other parts of the world. As an example, Sagheri et al. (2009) reported a social gradient in using preventive dental services among children of Ireland, but no such trend in DMFT of the same children. To justify such findings, one could blame the nature and shortcomings of the DMF Index or complexity of the risk factors for dental caries.

In the current study, social gradient could not been shown in DMFT or dmft of studied children. Further research revealed that similar conditions had been reported by others. As an example, Sagheri et al. (2009) reported a social gradient in using preventive dental services among children of Ireland, but no such trend in DMFT of the same children. To justify such findings, one could blame the nature and shortcomings of the DMF Index or complexity of the risk factors for dental caries.

DDE is probably the most important oral health indicator assessed in this study. Presence of DDE on teeth can be an index of both general and oral health. Many early childhood adverse health conditions and diseases can increase the risk of developing a DDE on permanent dentition. Despite the importance of DDE as a health indicator, few studies have tried to assess the relationship of the prevalence of DDE, especially on permanent teeth, with socio-economic factors. One of such studies has been conducted by Basha et al. that reports a significant negative association between the presence of DDE and socio-economic status of children, a finding that is very similar to what is shown in the current study.

The influence of socio-economic status on health condition means children have different life chances based on their birthplace, or area of living, even inside one city. If they live in a higher socio-economic zone, they would have a higher chance for better oral and general health in comparison to their peers in neighboring lower

Dataset 1. Raw data

http://dx.doi.org/10.5256/f1000research.8641.d120612

Data on age, sex, socioeconomic, anthropometric and oral health variables are provided.
As oral health and general health follow the social gradients, tackling health inequalities would need identifying and understanding the underlying causes of problems. Upstream measures would be needed to build a society that could reinforce good oral and general health. Future assessment of the relationship between social gradients in oral health and general health is recommended.

**Conclusion**

There are social gradients in general and oral health among primary school children of Shiraz, Iran. The gradient in oral health seems to follow the same pattern in general health.

**References**

**Consent**

Written informed consent for participation in the study was obtained from the parents of the children.

**Data availability**

**Author contributions**

The study was conceived and designed by AG, Ash, and RGW. AG and ASa carried out the research. AG analyzed the data. All authors were involved in preparation of the first draft. AG and ASa finalized the manuscript. The data for this study were extracted from a PhD thesis by AG under supervision of RGW and ASh. ASa was involved in data collection and preparation of the manuscript.

Ali Kazemian
Department of Community Oral Health, Mashhad School of Dentistry, Mahshad University of Medical Sciences, Mashhad, Iran

I found this article worth indexing. Well organized, well written.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

Competing Interests: No competing interests were disclosed.

Referee Report 24 May 2016
doi:10.5256/f1000research.9297.r13930

Myung Ki
Department of Preventive Medicine, School of Medicine, Eulji University, Daejeon, Korea, South

The theme of this paper is, to my mind, very interesting (socioeconomic inequalities in general and dental health) and various general and dental measures with trustable definition are plus. The design and data analysis seem acceptable to support the conclusion. Thus, I believe that this paper merits indexation, but there is a few points to be addressed / discussed more.

1. For anthropometric variables, authors describe: “Even after adjustments were made for sex and age, still all anthropometric variables: height (P < 0.001), weight (P < 0.001), BMI (P = 0.001) and leg length (P < 0.001) of children significantly increased as the socioeconomic status of area increased.”

   However, no actual results on this appear in the table and please check in which table the result is shown. If this finding is less important and authors decided not to present the data, please indicate that “data is not presented”.

2. It is not clear why two p values are presented in the table 1 and I think it would be four p-values per each column. Similarly, only two p-values were presented in the table 2, instead of four as to four measures. I am sorry, if misunderstanding is mine.
3. For presentation of table 1, I wonder whether the use of Odds Ratio is proper approach. I think instead of OR, presenting different proportions for three area groups and statistical test with Chi-square would be relevant and complementary to other results in table 1, for example, Chi-square test for “having at least one jobless parent” for three area levels.

4. Use of area level SEP could be more justifiable, if the parents are actual residents of the areas to which their siblings attend, if additional information of this kind is available.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.

**Competing Interests:** No competing interests were disclosed.

The manuscript reported very important subject in oral health’ field, seems sound and very well written. It is acceptable for indexation. I suggest the authors should address some studies regarding oral health and general health and also oral health and socio-economic factors which have been reported in Iran.

I have read this submission. I believe that I have an appropriate level of expertise to confirm that it is of an acceptable scientific standard.
